Parameterized Model Checking by enhancing the SPIN checker

SHANSHAN LIU, ANKIT GOEL, ABHIK ROYCHOUDHURY

National University of Singapore

Parameterized systems are characterized by the presence of a large (or even unbounded) number of behaviorally similar processes, and they often appear in distributed controllers and protocols. Verification of parameterized systems involves reasoning about unboundedly many processes and hence cannot be accomplished directly by model checking. In this work, we develop an abstraction refinement based verification framework for parameterized systems. We enhance the well-known SPIN model checker with process count abstractions to develop a time and memory efficient Linear-time Temporal Logic (LTL) model checker for parameterized systems. We also develop methods for automated detection of spurious counter-examples, and their elimination via abstraction refinement. The usability/scalability of our checker is demonstrated via the modeling and automated verification of several real-life parameterized control systems and protocols.

General Terms: Verification

Additional Key Words and Phrases: SPIN Model Checker, Abstraction Refinement

1. INTRODUCTION

Many distributed control systems contain a large number of concurrently running, behaviorally similar processes interacting among themselves, as well as with other processes. Examples of such control systems are common in automotive, avionics and other application domains. As an example consider a centralized controller disseminating traffic information to various flights in a flight control system. Or, consider a centralized registry enabling the communication among various devices (such as CD player, TV, GPS) in a modern car. The behaviorally similar processes in these systems are generally of the same process-type (e.g., the process-type of flights in a flight-control system). Furthermore, the number of processes in a process type is often unbounded when the system is designed, and fixed later when the system is deployed. For example, at design time we do not know how many incoming/outgoing flights a flight control system may need to deal with when it is deployed. It is necessary to verify crucial properties of the control system with unbounded number of flights, such that the verification results hold for any number of flights.
Concurrent systems with unboundedly many behaviorally similar processes of the same process type are known as *parameterized systems*. Parameterized systems typically consist of finitely many process types – the behavior of each process type being summarized by a finite-state transition system. The number of processes for (some of) the process types is unbounded — denoted as $\omega$. Verification of parameterized systems is beyond the realm of model checking since we need to reason about unboundedly many processes. Note that it is unnatural to fix the number of processes to an arbitrary constant, just for making their verification amenable to model checking. This is because it is in general difficult (not decidable) to compute a cutoff number on the number of processes such that the restricted system will exhibit all behaviors of the system with unbounded number of processes.

Most existing works on parameterized system verification have focused on developing (more) automated checking procedures. However, researchers have ignored the issues in developing a usable and efficient checker which can be used for debugging real-life parameterized control software, namely: (a) being supported by a powerful modeling language to describe non-trivial control systems and protocols, (b) time/space efficiency in checking, (c) spurious counter-example detection (the spurious behaviors arising from abstraction), along with abstraction-refinement, and (d) analysis of non-spurious counter-examples to determine a finite-state system exhibiting the same trace. In this paper, we address these issues.

We develop an abstraction-refinement based automated proof method for parameterized systems. Our abstractions (and their refinements) deal with the number of processes to keep track of, for process types in the system with unbounded number of processes. Thus, for every process type with unbounded number of processes — a *cutoff number* is assumed in the initial abstraction and then gradually refined by repeated application of abstract - modelcheck - refine steps. Since our abstractions in general lead to over-approximations of behavior, model checking of the abstracted system may lead to spurious counter-examples. We develop automated methods to (i) check whether a given counter-example trace is spurious, and (ii) refine our abstraction (by increasing cutoff numbers) to eliminate a given spurious counter-example. For non-spurious traces (traces which point to real errors), we develop heuristics to determine a system with a small, finite number of processes which exhibit the same counter-example trace. *Our method can be used for verifying Linear-time Temporal Logic (LTL) properties of parameterized systems, subject to few restrictions; these restrictions appear in Section 8.1.*

Similar to works on abstraction refinement based sequential software verification [Chaki et al. 2003; Beyer et al. 2007; Ball and Rajamani 2002], our proof method follows an abstract - verify - refine loop which is iterated. While those approaches deal with abstraction of program variables from unbounded data domains, our abstractions deal with unbounded number of processes. Our spurious counter-example check and refinement step is fully automated, thereby making our proof method *fully automated*. Since parameterized system verification is undecidable [Apt and Kozen 1986], our verification procedure may not terminate in general. However, this is not unexpected given the undecidability of the problem — existing works on abstraction refinement based software verification (such as [Chaki et al. 2003; Beyer et al. 2007; Ball and Rajamani 2002]) also cannot guarantee termination of the abstract-verify-refine loop. In our experiments on several real-life control systems and protocols, our verification procedure not only terminates, but also is highly efficient in terms of time and memory.
In terms of implementation, we modify the internals of the well-known SPIN model checker [Holzmann 2003; 1997] to integrate our proof method. Any designer familiar with SPIN, and its input language PROMELA, can use our method as a black-box to verify parameterized systems. We take advantage of powerful optimizations inside SPIN to develop an efficient checker for parameterized systems.

Contributions. The contributions of this paper are as follows.

—We develop a fully automated methodology for parameterized system verification via abstraction refinement. Given a LTL property $\varphi$, our proof method gradually discovers the cutoff numbers needed to prove $\varphi$ for each process type in the system with unbounded number of processes.

—As far as system modeling is concerned, we tie up with the rich PROMELA modeling language used in SPIN. Our goal here is pragmatic — since PROMELA/SPIN are widely used for system modeling/verification, this immediately increases the potential usability of our method. Indeed, we implement our proof method inside the verification engine of SPIN. Thus, any user familiar with PROMELA/SPIN can straightaway use our proof method for parameterized system verification. Moreover, all of the state-space optimizations already built inside SPIN enhance the efficiency of our checker.

—Last but not the least, experiments with our parameterized system checker implemented inside SPIN demonstrate its scalability in terms of time and memory. We have experimented our checker on large-scale parameterized control systems from the automotive/avionics domain as well as on well-known bus protocols (such as Futurebus+). We have also made our tool available for usage in research / teaching. The tool and its description can be obtained from http://www.comp.nus.edu.sg/~abhik/SPIN++/

In summary, we develop an abstraction refinement based automated proof method for parameterized systems, and integrate it with the mature SPIN model checking tool. This also enables rich modeling of parameterized systems using PROMELA, and experiments on large-scale parameterized control systems.
2. OVERVIEW

An outline of our verification framework appears in Figure 1. The verification procedure involves deriving an abstract verifier (based on model checker SPIN) corresponding to a given system model and property to be verified. Parameterized verification of the system proceeds by executing the abstract verifier thus generated. At the end of a verification run, either the verifier outputs “pass” – indicating no property violation in the system model, or a counter-example exhibiting the property violation. Since, in general our abstraction is an over-approximation of concrete behaviors, a counter-example obtained from the abstract verifier can be spurious. Thus, a spuriousness check is performed on the counter-example obtained. If a counter-example is not spurious, a system with finite number of processes exhibiting the same counterexample is generated. Otherwise, we refine our abstraction to prevent the spurious counter-example from occurring in the subsequent verification runs. Since parameterized system verification is undecidable [Apt and Kozen 1986], the abstraction-refinement loop shown in Figure 1 is not guaranteed to terminate. Hence, user may specify a bound on the number of refinement steps undertaken.

We now illustrate the various steps in our verification framework with the help of a small example. Consider a system model consisting of a single process type $p_1$ with no local variables. The transition system corresponding to process type $p_1$ is shown in Figure 2, where for $i \in [0, 3]$, $l_i$ represents a control location, and $\alpha_0 - \alpha_2$ represent the actions executed by a $p_1$-process. Thus, for example, a process of type $p_1$ can move from location $l_0$ to $l_1$ by executing action $\alpha_0$. Assume now, that we want to verify certain properties for this system model for any number of $p_1$ processes. Let us consider an unbounded number of $p_1$ processes which are initially in the state $l_0$.

In our abstract verification we only maintain the count of processes in various local states, and not their individual states or identities. If the process count is unbounded in some state, it is represented as $\omega$ during abstract verification. Further, a user-provided $p_1$ specific cutoff parameter (called $cut_{p_1}$) is used, such that $\omega$ represents greater-than or equal-to $cut_{p_1}$ $p_1$-processes. Then, (a) if a $p_1$ process moves in to a state with $cut_{p_1}$ number of processes, the process count of that state becomes $\omega$, and (b) if a $p_1$ process moves out of a state with currently $\omega$ number of processes, there remains either $\omega$ or $cut_{p_1}$ number of processes in the source state.

We now consider verification of the given system against the following LTL property: $\neg(\alpha_0 \land X \alpha_1 \land X X \alpha_2)$. It specifies that the action sequence $\sigma = \alpha_0 \alpha_1 \alpha_2$ can never occur in a system execution. Initially, let $cut_{p_1} = 1$. This means in the abstract verification, the count of processes in any state $l_i$ is either 0 (denoting no processes in $l_i$) or $\omega$ (denoting one or more processes in $l_i$). Abstract verification returns a counter-example trace, which is $\sigma$ itself. The number of processes in different states during abstract execution of $\sigma$ are shown in the following.

<table>
<thead>
<tr>
<th>Control state</th>
<th>Number of processes ($cut_{p_1} = 1$)</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Initially</td>
</tr>
<tr>
<td>$l_0$</td>
<td>$\omega$</td>
</tr>
<tr>
<td>$l_1$</td>
<td>0</td>
</tr>
<tr>
<td>$l_2$</td>
<td>0</td>
</tr>
<tr>
<td>$l_3$</td>
<td>0</td>
</tr>
</tbody>
</table>

However, it is easy to see that the counter-example trace $\sigma$ cannot be exhibited in any
concrete system. At least two occurrences of $\alpha_0$ are required for $\alpha_1$ and $\alpha_2$ to be executed subsequently. Hence, $\sigma$ is spurious. Trace $\sigma$ can be exhibited in the abstract system because after a single occurrence of $\alpha_0$, the process count in $l_1$ becomes $\omega$ (since $cut_{p_1} = 1$). Consequently, both $\alpha_1$ and $\alpha_2$ can be executed from $l_1$. In order to prevent this spurious counter-example, we refine our abstraction by increasing the cutoff number $cut_{p_1}$ to 2. This means in the abstract verification, the count of processes in any state $l_i$ is now either 0 (denoting no processes in $l_i$) or 1 (denoting exactly one process in $l_i$) or $\omega$ (denoting more than one process in $l_i$). Now, after a single occurrence of $\alpha_0$ the process count at $l_1$ will become 1 (and not $\omega$), which is not sufficient to execute both $\alpha_1$ and $\alpha_2$. As a result, $\sigma$ can no longer occur in abstract execution.

As another example, consider the LTL property $\neg(\alpha_0 \land X\alpha_1)$, which specifies that the action sequence $\sigma' = \alpha_0\alpha_1$ can never occur. Similar to the previous example, here also the abstract verification run returns a counter-example, which is $\sigma'$. However, unlike above, $\sigma'$ is not spurious and can be exhibited in a concrete system. Further, we can easily see that $\sigma'$ can be exhibited in a concrete system with only a single process of type $p_1$. Later, (in Section 6.2) we describe a heuristic procedure for deriving such a smaller concrete system corresponding to a non-spurious counter-example for debugging purposes.

3. MODELING

We use (a fragment of) PROMELA, the input language of SPIN, for modeling the system to be verified. This enables a user already familiar with SPIN, and hence PROMELA, to readily use our parameterized verification framework.

We fix a finite set of process types $P$ with $p,q$ ranging over $P$. Each process type in $P$ corresponds to a process declaration via $proctype$ in PROMELA. Various processes, which are the instances of process types in $P$, are described by means of finite-state labeled transition systems. We also fix a finite alphabet of $actions$ $\Sigma$ with $\alpha, \beta$ ranging over $\Sigma$. Actions in $\Sigma$ represent basic PROMELA statements, such that an action in $\Sigma$ may correspond to a send/receive event, an assignment, an assertion, or creation of an instance of a process type. Various processes can communicate via synchronous message exchange or through shared variables. With each action $\alpha \in \Sigma$, we associate— (a) a pre-condition $Pre\alpha$ specifying a boolean condition to be satisfied by a system state for executing $\alpha$, and (b) a post-condition $Post\alpha$ capturing the system state update upon execution of $\alpha$.

We note here that PROMELA allows inter-process communication via shared variables, synchronous message passing as well as asynchronous message passing. In our modeling, we restrict ourselves to systems which do not have asynchronous message passing.

In order to model the internal states and computations performed by processes, we fix a set of local variables $Var_{p}$ for each process type $p \in P$, and a set of global variables
value in its finite domain. Each variable $x \in \text{Var}_p \cup \text{Var}_G$ takes values from a finite domain $D_x$. Thus, a variable valuation refers to a mapping of each variable to a value in its finite domain.

**Definition 1 System Model.** A system model is a structure

$$S = (\text{Var}_G, v^p_{\text{in}}, TS_p)$$

consisting of (i) a set of global variables $\text{Var}_G$, (ii) their initial valuation $v^p_{\text{in}}$ and (iii) a $p$-indexed family of transition systems

$$TS_p = \{TS_p = (L_p, \to_p, l^p_{\text{in}}, \text{Var}_p, v^p_{\text{in}})\}_{p \in \mathcal{P}}$$

such that for each $p \in \mathcal{P}$,

- $L_p$ is a finite set of $p$’s control states,
- $\to_p \subseteq L_p \times \Sigma \times L_p$ is a transition relation for $p$,
- $l^p_{\text{in}} \in L_p$ is the initial control state of $p$, and
- $\text{Var}_p$ is the set of local variables in $p$, and $v^p_{\text{in}}$ is their initial valuation.

Consider the example in Figure 2, which consists of a single process type $p_1$ with no local variables. The actions appearing in this specification are $\Sigma = \{a_0, a_1, a_2\}$, and the transition system of $p_1$ is represented as:

$$TS_{p_1} = \{(l_0, l_1, l_2, l_3) \to (l_0, l_1, l_2, l_3)\}$$

where $\to_{p_1} = \{(l_0, a_0, l_1), (l_1, a_1, l_2), (l_1, a_2, l_3)\}$.

Let $\text{OBJ}_p$ denote a finite non-empty set of processes populating process type $p$. We require that $\text{OBJ}_p \cap \text{OBJ}_q = \emptyset$ whenever $p \neq q$. We set $\text{OBJ} = \bigcup_{p \in \mathcal{P}} \text{OBJ}_p$ and let $o, o'$ range over $\text{OBJ}$. Further, each variable $x$ in the system has a finite domain $D_x$. Hence, we let $Val_G$ be a mapping for each global variable to its finite domain, and $Val_p$ be a mapping for each variable in process type $p$ to its finite domain. We denote $Val_P = \bigcup_{p \in \mathcal{P}} Val_p$.

For each process type $p$, let $S_p \subseteq L_p \times Val_p$ represent the execution states of $p$, where $L_p$ is the set of $p$’s control states describing $TS_p$ and $Val_p$ is the set of valuations of variables in $\text{Var}_p$. The initial $p$-state is given by $s^p_{\text{in}} = (l^p_{\text{in}}, v^p_{\text{in}})$, where $l^p_{\text{in}} \in L_p$ is the initial $p$-control state and $v^p_{\text{in}}$ is an initial valuation of variables in $p$. We set $S_P = \bigcup_{p \in \mathcal{P}} S_p$ and let $s, s'$ range over $S_P$. Again, consider the example shown in Figure 2. The initial state corresponding to process type $p_1$ is $s^p_{\text{in}} = (l_0, \epsilon)$, where the variable valuation part is empty (represented as $\epsilon$) since $p_1$ has no local variables.

In order to define the operational semantics of a system model, we define the notion of a configuration capturing the global system state during execution. Since we are defining a system configuration where the system consists of concrete processes, we call it a “concrete configuration”. This is to distinguish this notion from the state space abstraction and the abstract configurations we will introduce later.

**Definition 2 Concrete Configuration.** Let $S = (\text{Var}_G, v^p_{\text{in}}, TS_p)$ be a given system model. A concrete configuration of $S$ is a pair of mappings $(v_g, M)$, where $v_g$ is a valuation of global variables $\text{Var}_G$, and mapping $M : S_P \to 2^{\text{OBJ}}$ is defined such that:

- $M(s) \subseteq \text{OBJ}_p$ for every $p$ and every $s$ in $S_p$,
- $M(s) \cap M(s') = \emptyset$ whenever $s \neq s'$, and
—\bigcup \{ M(s) \mid s \in S_p \} = OBJ_p \text{ for every } p.

Let \( CFG \) denote the set of all concrete configurations.

Given a system model \( S = (Var_G, v^0, TS_P) \) and an initial set of processes \( OBJ^0 \) for each process type \( p \), the initial configuration of \( S \) is defined as \( C_{in} = (v^0, M^{in}) \), where (a) \( v^0 \) is an initial valuation of global variables, and (b) for every \( p \in \mathcal{P} \) and every \( s \in S_p \), \( M^{in}(s) = OBJ^0 \) if \( s = s^0_p \), otherwise \( M^{in}(s) = \emptyset \). For the example shown in Figure 2, suppose two instances (say, \( o_1, o_2 \)) of process type \( p1 \) are created initially. Since, \( p1 \) has no local variables, all possible execution states of \( p1 \) are determined by its local control states, \( i.e. S_{p1} = \{s_0, s_1, s_2, s_3\} = S_P \), where \( s_1 = (l, \epsilon) \), with \( \epsilon \) representing an empty variable valuation. Also, since there are no global variables in this example, the global variable valuations in this example will also be empty (or, \( \epsilon \)). Then, the initial configuration in this case is given by: \( (\epsilon, M^{in}) \), where \( M^{in}(s_0) = \{o_1, o_2\} \) and \( M^{in}(s_1) = M^{in}(s_2) = M^{in}(s_3) = \emptyset \).

During execution, system moves from one concrete configuration to another by participating in an action from \( \Sigma \). If a process \( o \) of type \( p \) moves from state \( s_1 \in S_p \) at concrete configuration \( C = (v, M) \) to state \( s_2 \in S_p \) by executing an action \( \alpha \in \Sigma \), the processes at the resulting configuration \( C' = (v', M') \) are determined as follows. Let \( I : S_P \rightarrow 2^{OBJ} \) be an intermediate mapping s.t.

—If \( s_1 \neq s_2 \), then
\[
I(s_1) = M(s_1) - \{o\},
I(s_2) = M(s_2) \cup \{o\},
I(s) = M(s) \text{ for } s \in S_P \setminus \{s_1, s_2\}.
\]
—Otherwise, \( \forall s \in S_P, I(s) = M(s) \).

The relationship between the resulting mapping \( M' \) at configuration \( C' \) and the intermediate mapping \( I \) is as follows — (i) If \( \alpha \) does not create new process, then \( M' = I \), (ii) Otherwise, suppose by executing \( \alpha \), a new process \( o_q \) of type \( q \) is created and starts its execution from an execution state \( s_q \in S_Q \). Then, we have

—\( M'(s_q) = I(s_q) \cup \{o_q\} \);
—\( M'(s) = I(s) \), for all \( s \neq s_q \).

We use relation \( update_c(s_1, M, \alpha, s_2, M') \) to denote that the mapping \( M' \) can be derived from \( M \) due to migration of a process from state \( s_1 \) to \( s_2 \) by executing \( \alpha \). The transition relation for the concrete execution \( \rightarrow \subseteq CFG \times \Sigma \times CFG \) is defined as follows.

**Definition 3** Concrete Transition Relation \( \rightarrow \). Let \( C = (v, M), C' = (v', M') \in CFG \) be concrete configurations of a system model \( S = (Var_G, v^0, TS_P) \), and \( \alpha \in \Sigma \) be an action. Then \( (C, \alpha, C') \in \rightarrow \Leftrightarrow \exists p \in \mathcal{P}, \exists s = (l, v), s' = (l', v') \in S_p, s.t.

(1) \( (l, \alpha, l') \in \rightarrow_p \) is a transition in \( TS_p \).
(2) \( |M(s)| \geq 1 \), i.e. there is at least one process at state \( s \).
(3) \( v \) and \( v_q \) satisfy the pre-condition \( Pre_\alpha \).
(4) \( v'(v_q') \) is the effect of post-condition \( Post_\alpha \) on \( v(v_q) \). Here \( v_q' \) represents an update of global variables \( Var_G \), which can later be read/updated by other processes, thus allowing for shared variable communication.
Each box is of the form: \[M(s_0), M(s_1), M(s_2), M(s_3)\]

Fig. 3. Sample Concrete Transition Relation

(5) If last action executed was a send\(^1\) event, then \(\alpha\) must be the corresponding receive event. If the matching receive cannot be executed, then the last executed send event is rolled back, and some other enabled action is executed in its place.

(6) The relation \(update_c(s, M, \alpha, s', M')\) holds as described above.

For the example shown earlier in Figure 2, we present its state exploration graph depicting all reachable concrete configurations in Figure 3. Since, no global variables are used in this example, we omit their valuation from a state representation. In each global state, the processes presented in various execution states of process type \(p_1\) are shown, which is the only process type appearing in this example. Also, for \(i = 0, 1, 2, 3\), \(s_i = (l_i, \epsilon)\), where \(l_i\) is the local control state of \(p_1\) and \(\epsilon\) represents an empty local variable valuation. Initially, two processes of type \(p_1\) are created, which are represented as \(o_1\) and \(o_2\) residing at state \(s_0 = (l_0, \epsilon)\). Then, either \(o_1\) or \(o_2\) can be chosen to execute \(\alpha_0\), following by the execution of \(\alpha_0\) from the other process, or the execution of either \(\alpha_1\) or \(\alpha_2\) from the same process, resulting in different paths in the state exploration graph ending in two configurations with \(o_1\) residing at state \(s_2\) and \(o_2\) residing at state \(s_3\), or vice versa.

4. STATE SPACE ABSTRACTION

4.1 Core Abstraction

For efficient verification of parameterized systems, we employ an abstract state space representation, where the core idea is to group together processes in a process type which are in similar states. However, the grouping of processes is not fixed statically, but changes dynamically with the state space construction. Two processes of type \(p\) are similar if and only if they are in the same state \(s = (l, v) \in S_p\), where \(l\) is the control state in \(TS_p\) (the transition system of \(p\)) and \(v\) is a valuation of \(p\)'s variables. Based on this, the key idea in our abstraction is that, if two processes are in the same execution state we need to distinguish between them via their process ids. Hence, our abstraction systematically

\(^1\)Recall that, we only consider synchronous message communication.
exploits this observation by only maintaining the count of processes in each execution state in $\bigcup_{p \in P} S_p$.

Along with the state space abstraction as described above, we allow a process-type to have an unbounded number of processes in our abstract execution semantics. If a process type $p$ initially has unbounded number of processes, or if $p$ has unbounded number of processes due to dynamic process creation during execution – the user provides an input parameter $cut_p \in \mathbb{N}$. By default $cut_p$ is set to 1. Then, for any number of processes equal to or greater than $cut_p$, we represent it as $\omega$.

For a process type $p$ with initially fixed number of processes, and no dynamic process creation – the process counts never become $\omega$ and the number of processes is fixed. Hence, the cutoff number is not an issue! We can simply assume the cutoff number to be a number greater than the number of $p$-processes by default.

Based on our abstract state representation, we now define the notion of an abstract configuration.

**Definition 4 Abstract Configuration.** Let $\mathcal{S} = (\mathcal{V}ar_G, v_{in}^p, TS_P)$ be a given system model and for each process type $p \in P$, $N_p^a$ denote the number of $p$-processes during execution. An abstract configuration is defined as a pair of mappings $(v_{in}^p, M_a)$, where $v_{in}^p \in Val_G$ is a valuation of global variables and $M_a : S_P \rightarrow \mathbb{N} \cup \{\omega\}$ s.t. $\forall p \in P, \sum_{s \in S_p} M_a(s) = N_p^a$.

Let $CFG_{abs}$ denote the set of all abstract configurations.

Let $\mathcal{S} = (\mathcal{V}ar_G, v_{in}^p, TS_P)$ be a given system model with $N_p$ number of processes of type $p \in P$. Then, the initial abstract configuration of $\mathcal{S}$ is defined as $C_a^{in} = (v_{in}^p, M_a^{in})$, where $v_{in}^p$ is the initial valuation of global variables, and $M_a^{in}$ is the initial valuation of global variables.

During execution, system moves from one abstract configuration to another by executing an action from $\Sigma$. If a process of type $p$ moves from state $s_1 \in S_p$ at configuration $C_a = (v, M_a)$ to state $s_2 \in S_p$ by executing an action $\alpha \in \Sigma$, the process counts at a resulting configuration $C_a' = (v', M_a')$ are determined as follows. Let $I_a : S_P \rightarrow \mathbb{N} \cup \{\omega\}$ be an intermediate mapping, s.t.

- If $s_1 \neq s_2$, then
  \[
  I_a(s_1) = \begin{cases} 
  M_a(s_1) - 1, & \text{if } M_a(s_1) < cut_p \\
  cut_p - 1 \text{ or } \omega, & \text{if otherwise.} 
  \end{cases}
  \]
  \[
  I_a(s_2) = \begin{cases} 
  M(s_2) + 1, & \text{if } M(s_2) < cut_p - 1 \\
  \omega, & \text{otherwise.} 
  \end{cases}
  \]
  \[I_a(s) = M(s), \text{ for } s \in S_P \setminus \{s_1, s_2\} \tag{1}\]

- Otherwise, $\forall s \in S_P : I_a(s) = M_a(s)$.

If $\alpha$ does not create new process, then $M_a' = I_a$. Otherwise, suppose by executing $\alpha$, a process of type $q$ is created and starts its execution from state $s_q \in S_q$. Then we set

- for state $s_q$,
  \[
  M_a'(s_q) = \begin{cases} 
  I_a(s_q) + 1, & \text{if } I_a(s_q) < cut_q - 1 \\
  \omega, & \text{otherwise.} 
  \end{cases}
  \tag{2}
  \]

- for $s \in S_P \setminus \{s_q\}$, $M_a'(s) = I_a(s)$.
We use the relation $update_\alpha(s_1, M_a, \alpha, s_2, M_a')$ to denote that mapping $M_a'$ can be derived from $M_a$ due to migration of a process from state $s_1$ to $s_2$ by executing action $\alpha$.

Note that, when there are $\omega$ processes in the source state $s_1$ at configuration $C_a = (v, M_a)$ (i.e. $M_a(s_1) = \omega$) and the destination state $s_2$ is different from $s_1$, then two possible configurations may result from $C_a$ as described above (see Eqs. (1)). If $C_a' = (v', M_a')$ represents the resulting abstract configuration, then process count in state $s_1$ at configuration $C_a'$ (i.e. $M_a'(s_1)$) is either (i) $\omega$, assuming there were greater than cut$_p$ processes in $s_1$ at configuration $C_a'$, or (ii) cut$_p - 1$, assuming there were exactly cut$_p$ processes in $s_1$ at configuration $C_a'$. Given the above notion of abstract configurations $CFG_{abs}$, we define an abstract transition relation $\leftarrow_a \subseteq CFG_{abs} \times \Sigma \times CFG_{abs}$ as follows.

**Definition 5 Abstract Transition Relation $\leftarrow_a$.** Let $S = (Var_G, v_{in}, TS_P)$ be a system model, $C_a = (v_g, M)$, $C_a' = (v_g', M_a') \in CFG_{abs}$ be its abstract configurations, and $\alpha \in \Sigma$ is an action. Then $(C_a, \alpha, C_a') \in \rightarrow_a$ if and only if $\exists p \in P, \exists s = (l, v), s' = (l', v') \in S_p$, s.t.

1. $(l, \alpha, l') \in \rightarrow_p$ is a transition in $TS_P$.
2. $M_a(s) \geq 1$, i.e. there is at least one process in $s$.
3. $v$ and $v_g$ satisfy the pre-condition $Pre_\alpha$.
4. $v'(v_g')$ is the effect of post-condition $Post_\alpha$ on $v(v_g)$. Here $v_g'$ represents an update of global variables $Var_G$, which can later be read/updated by other processes, thus allowing for shared variable communication.
5. If last action executed was a send$^2$ event, then $\alpha$ must be the corresponding receive event. If the matching receive cannot be executed, then the last executed send event is rolled back, and some other enabled action is executed in its place.
6. The relation $update_\alpha(s, M_a, \alpha, s', M_a')$ holds.

$^2$Recall that, we only consider synchronous message communication.

For illustration, we again consider the example in Figure 2. Assume that, an unbounded number of processes \( \omega \) of type \( p1 \) are created initially, and the default cutoff number \( \text{cut}_{p1} = 1 \) is used. For \( i \in [0, 3] \), \( s_i = (l_i, \epsilon) \), where \( l_i \) is a control location in \( T S_{p1} \), and since \( p1 \) has no local variables, their valuation is represented as \( \epsilon \). Further, assuming that there are no global variables, we omit global variable valuation from the abstract configurations. Hence, we represent the abstract configurations for this system by a mapping \( M_a \), such that \( M_a(s_i), i \in [0, 3] \) represents the number of \( p1 \) processes in state \( s_i \). Its partial abstract state exploration graph is shown in Figure 4. Initially, action \( \alpha_0 \) is executed by a process in state \( s_0 \) from the initial configuration \( (C_0^{in}) \), resulting in two different configurations \( C_1 \) and \( C_2 \). The configuration \( C_1^a \) (towards left) corresponds to the case where \( \omega \) represents exactly one process in state \( s_0 \) at \( C_1^{in} \), while configuration \( C_2^a \) (towards right) corresponds to the case where \( \omega \) represents two or more processes in state \( s_0 \) at \( C_1^{in} \). Further, all actions \( \alpha_0, \alpha_1 \) and \( \alpha_2 \) are enabled at configuration \( C_1^a \), while only \( \alpha_1 \) and \( \alpha_2 \) are enabled at configuration \( C_2^a \). The paths following these abstract configurations are explored in a similar manner.

### 4.2 Soundness of Abstraction

We now show the soundness of proof search over the abstract state space. Before proceeding to the proof, we first define a relation \( \equiv \subseteq CFG \times CFG_{abs} \) as follows.

**Definition 6.** For all \( C_c = (v^g_c, M_c) \in CFG \) and \( C_a = (v^g_a, M_a) \in CFG_{abs} \), \( C_c \equiv C_a \iff v^g_c = v^g_a \) and \( \forall p \in P, \forall s \in S_p, M_a(s) \geq |M_c(s)| \).

We now prove that our abstract execution semantics is an over-approximation of the concrete execution semantics.

**Theorem 1.** Let \( \sigma \) be a possibly infinite sequence of actions that can be exhibited in the concrete execution of a system model \( S \) with initially \( N^c_p \in \mathbb{N} \) processes of type \( p \). Then, \( \sigma \) can be exhibited in the abstract execution of \( S \) with initially \( N^a_p \) processes of type \( p \), where either \( N^c_p = \omega \) or \( N^a_p \in \mathbb{N} \) s.t. \( N^c_p \geq N^a_p \).

**Proof.** In order to prove this theorem, we consider the following property. Recall that \( \leftrightarrow \) and \( \rightarrow_a \) denote the concrete and abstract transition relations respectively.

**Property 1:**

\[
\forall (C_c, \alpha, C'_c) \in \leftrightarrow, \forall C_a \in CFG_{abs}, C_c \equiv C_a \Rightarrow \exists (C_a, \alpha, C'_a) \in \rightarrow_a, \text{ s.t. } C'_c \equiv C'_a.
\]

We prove the above property as follows. Let \( C_c = (v^g_c, M_c), C'_c = (v^g_c, M'_c) \in CFG \), and \( C_a = (v^g_a, M_a) \in CFG_{abs} \), s.t. \( (C_c, \alpha, C'_c) \in \leftrightarrow \) and \( C_c \equiv C_a \). Suppose by executing \( \alpha \) in concrete execution, a process \( o \) of type \( p \) moves from state \( s_\alpha \) to state \( s'_\alpha \). Hence, \( update_c(s_\alpha, M_c, \alpha, s'_\alpha, M'_c) \) from Def. 3 holds.

Since \( C_c \equiv C_a \), by Def. 6, \( v^g_c = v^g_a \); moreover, \( M_a(s_\alpha) \geq |M_c(s_\alpha)| \) and \( M_a(s'_\alpha) \geq |M_c(s'_\alpha)| \). Thus, action \( \alpha \) can be executed by choosing a process from state \( s_\alpha \) in the abstract execution. Let \( C'_a = (v^g_a, M'_a) \) be the resulting abstract configuration. Without loss of generality, we assume that \( s_\alpha \neq s'_\alpha \).

If \( M_a(s_\alpha) \in \mathbb{N} \), by the definition of \( update_a \) and \( update_c \) (ref. Sections 3 and 4), we have intermediate mappings \( I'_c(s_\alpha) = I_c(s_\alpha_{\alpha}) - \{ o \} \) and \( I'_a(s_\alpha) = I_a(s_\alpha) - 1 \). Now, we consider the following cases based on action \( \alpha \).
In abstract execution, the process counts in a process type concrete execution semantics) iff the following conditions hold—

1. If \( \alpha \) does not create new process and \( s_\alpha \neq s'_\alpha \), then \( M'_a(s_\alpha) = I'_a(s_\alpha) \) and \( M'_c(s_\alpha) = I'_c(s_\alpha) \). Since \( M_a(s_\alpha) \geq |M_c(s_\alpha)| \), we have \( M'_a(s_\alpha) \geq |M'_c(s_\alpha)| \).

2. If, by executing \( \alpha \), a new process \( o_q \) of type \( q \) is created and starts its execution at state \( s_q \), then we have \( M'_a(s_q) = M_c(s_q) \cup \{ o_q \} \) and \( M'_c(s_q) = M_a(s_q) + 1 \). Since \( M_a(s_\alpha) \geq |M_c(s_\alpha)| \), we have \( M'_a(s_\alpha) \geq |M'_c(s_\alpha)| \).

If \( M'_a(s_\alpha) = \omega \), then by the definition of \( \text{update}_a \), we always allow the possibility that \( M'_a(s_\alpha) = \omega \). By the similar argument as in the case of \( M_a(s_\alpha) \in \mathbb{N} \), we have \( M'_a(s_\alpha) \geq |M'_c(s_\alpha)| \). Similar argument applies to \( M'_c(s'_\alpha) \). Finally since the effect of action \( \alpha \) is the same on \( v^q_a \) and \( v^q_c \), we have \( v^q_a = v^q_c \). Therefore, \( C'_c \simeq C'_a \).

Property 1 establishes that \( \simeq \) is a simulation relation. To complete the proof of the main theorem, we only need to show that the initial configurations in the concrete and abstract execution semantics are related by \( \simeq \). This is indeed the case, and this concludes the proof.

4.3 When is the abstraction exact?

We have now established that our abstract execution semantics is an over approximation — any execution trace exhibited in the concrete execution semantics is also exhibited in the abstract execution semantics. Further, our abstract execution semantics is exact (i.e., any sequence of actions allowed by the abstract execution semantics is also allowed by the concrete execution semantics) iff the following conditions hold–

C1. In abstract execution, the process counts in a process type \( p \) are always represented using a natural number (i.e. they never become \( \omega \)) and are updated following the usual arithmetic rules. Note that \( cut_p \) does not play any role in this case.

C2. For each process type \( p \), the initial number of processes in abstract execution \( (N^a_p) \) is equal to the initial number of processes in the concrete execution \( (N^c_p) \), i.e. \( N^a_p = N^c_p \).

**DEFINITION 7.** Let \( \text{CFG}_a \) (\( \text{CFG}_c \)) be the set of abstract (concrete) configurations of system model \( S \). Then for all \( C_a = (v^a, M_a) \in \text{CFG}_a \) and \( C_c = (v^c, M_c) \in \text{CFG} \), \( C_a \simeq_a C_c \) iff \( v^a = v^c \) and \( \forall s \in S_p \), \( (M_a(s) = |M_c(s)|) \).

**THEOREM 2.** Let \( \sigma = \alpha_0 \alpha_1 \ldots \) be a possibly infinite action sequence exhibited in the abstract execution of \( S \) satisfying C1, then \( \sigma \) can be exhibited in the concrete execution of \( S \) satisfying C2, and for \( i \geq 0 \), \( C^a_i \simeq_a C^c_i \), where \( C^a_i \) (\( C^c_i \)) is the abstract (concrete) configuration before the abstract (concrete) execution of \( \alpha_i \).

**PROOF.** In order to prove this theorem, we consider the following property. The \( \leftrightarrow \) and \( \rightarrow_a \) denote the concrete and abstract transition relations respectively.

**Property 2:**
\( \forall(C_a, \alpha, C'_a) \in \rightarrow_a, \forall C_c \in \text{CFG}, C_a \simeq_a C_c \Rightarrow \exists(C_c, \alpha, C'_c) \in \leftrightarrow, \text{ s.t. } C'_a \simeq_a C'_c. \)

We prove the above property as follows. Let \( C_a = (v^a, M_a), C'_a = (v'^a, M'_a) \in \text{CFG}_a \), and \( C_c = (v^c, M_c) \in \text{CFG} \), s.t. \( (C_a, \alpha, C'_a) \in \rightarrow_a \) and \( C_a \simeq_a C_c \). Suppose by executing action \( \alpha \) in the abstract execution, a process of type \( p \) moves from state \( s_a \) to \( s'_a \), where \( s_a, s'_a \in S_p \). Since \( C_a \simeq_a C_c \), we have \( v^a = v^c \) and \( \forall s \in S_p \), \( (M_a(s) = |M_c(s)|) \), which implies that \( \forall s \in S_p \), \( M_a(s) \in \mathbb{N} \). Hence, by the definition of \( \text{update}_a \), we have intermediate...
mappings \( I'_c(s_{a}) = M_c(s_{a}) - 1 \) and \( I'_c(s'_{a}) = M_c(s'_{a}) + 1 \). Moreover \( \alpha \) can be executed by a process \( o_p \) of type \( p \) at state \( s_{a} \) in the concrete execution, which results in the intermediate mappings \( I'_c(s_{a}) = M_c(s_{a}) - \{o_p\} \) and \( I'_c(s'_{a}) = M_c(s'_{a}) + \{o_p\} \). Therefore, we have \( I'_a(s_{a}) = |I'_c(s_{a})| \) and \( I'_a(s'_{a}) = |I'_c(s'_{a})| \). Now, based on the characteristic of action \( \alpha \), we consider the following cases:

1. If \( \alpha \) does not create new process, then for abstract execution, we have \( M'_a(s_{a}) = I_a(s_{a}) \), \( M'_a(s'_{a}) = I_a(s'_{a}) \); and for concrete execution, we have \( M'_c(s_{a}) = I_c(s_{a}) \), \( M'_c(s'_{a}) = I_c(s'_{a}) \). Therefore, \( M'_a(s_{a}) = |M'_c(s_{a})| \), \( M'_a(s'_{a}) = |M'_c(s'_{a})| \).

2. If, by executing \( \alpha \), a new process of type \( q \) is created and starts its execution at local state \( s_{q} \). Moreover, in concrete execution, this new process is identified as \( o_q \). Then, in abstract execution, we have \( M'_a(s_{a}) = I_a(s_{a}) + 1 \), and for all other \( s \in S_F \), \( M'_a(s) = I_a(s) \). In concrete execution, we have \( M'_c(s_{a}) = I_c(s_{a}) \), \( M'_c(s_{a}) = I_c(s_{a}) \), and for all other \( s \in S_P \), \( M'_c(s) = I_c(s) \). Therefore, we have \( M'_a(s_{a}) = |M'_c(s_{a})| \), \( M'_a(s'_{a}) = |M'_c(s'_{a})| \).

Finally, the effect of \( \alpha \) is the same on \( v^a_{\omega} \) and \( v^a_{\omega} \). Therefore, we have \( C'_a \simeq C'_a \).

Property 2 establishes that \( \simeq_{a} \) is a simulation relation. It is easy to see that \( C'_a \simeq_{a} C'_a \), i.e. the initial configurations in the abstract and concrete execution semantics are related by \( \simeq_{a} \). This concludes the proof. \( \square \)

5. EXTENDING ABSTRACTION WITH COUNT VARIABLES

In the previous section we discussed our state space abstraction which involved abstracting away process ids. From the real life case studies that we have modeled for our experiments, we observe that this counter abstraction alone is not sufficient for modeling most of these examples. These examples generally involve a process (e.g. \( \text{controller} \)) that needs to communicate with, and maintain a count of processes of another type (e.g. \( \text{several clients} \)). Then, if we intend to verify a system which has an unbounded number of processes, say of type \( p \), we cannot use a variable with a finite domain to keep a count of \( p \)-processes.

5.1 Extended Abstraction Scheme

In order to keep track of the number of processes of type \( p \) with an unbounded number of processes, we introduce \( \text{process-count} \) variables having the domain \( \mathbb{N} \cup \{\omega\} \). We denote the set of all process-count variables as \( Var^\omega \). For a process-count variable, we only allow assignment operation that initializes it with a constant value or \( \omega \), as well as operations that increment or decrement its value by 1, and obey the following execution semantics\(^3\). For a process-count variable \( v \in Var^\omega \) used for counting processes of type \( p \):

\[
\begin{align*}
v++ & = \begin{cases} 
v + 1, & v < \text{cut}_p - 1 \\
\omega, & \text{otherwise.}
\end{cases} \\
v-- & = \begin{cases} 
v - 1, & v < \text{cut}_p \\
\text{cut}_p - 1 \text{ or } \omega, & \text{otherwise.}
\end{cases}
\end{align*}
\]

Moreover, \( v \) can be involved in a boolean expression: \( B \equiv v \text{ Relop } c \), where \( \text{Relop} \) is a relational operator and \( c \in \mathbb{N} \). Here, we only consider the case where \( \text{Relop} \) is \( \leq \). If

\(^3\)The abstract semantics can be similarly extended to support increment/decrement of a process count variable by any constant number \( c \). The case \( c = 1 \), worked out here, is most common.
\( v \in [0, \text{cut}_p] \). \( B \) evaluates to \textit{true} if \( v \leq c \), and \textit{false} otherwise. If \( v = \omega \) and \( c < \text{cut}_p \), then \( B \) is \textit{false}. Otherwise, if \( v = \omega \) and \( c \geq \text{cut}_p \), then we non-deterministically allow \( B \) to be either true or false. Various other relational operators are considered in a similar manner.

Thus, if process type \( p \) has \( \omega \) processes in abstract execution, the value of \( v \) lies in the domain \([0, \text{cut}_p) \cup \{\omega\}\), where \( \omega \) indicates the value of \( v \) to be \text{cut}_p \) or greater. Further, when \( v \) is decremented by one (i.e. \( v - 1 \)), if the original value of \( v \) is \( \omega \), then the resulting value of \( v \) is non-deterministically chosen to be either \text{cut}_p - 1 \) or \( \omega \). The former (latter) choice corresponds to the possibility that value of \( v \) was equal-to (greater-than) \text{cut}_p.

In PROMELA, a process-count variable used for counting processes of type \( p \), is declared using the following syntax—\textit{‘abs.p.X’}, where \( p \) is the process-type and \( X \) is any valid string allowed in a variable name in PROMELA. This specific format allows the verifier to identify and update these variables as per the rules described above.

Since the domain of variable \( x \in \text{Var}^\omega \) includes the unbounded value represented as \( \omega \), to distinguish it from the concrete domain of \( x \), i.e. \( D_x = (\mathbb{N} \cup \{\omega\}) \), we represent the abstract domain as \( D_a^x \) (i.e. \( \mathbb{N} \cup \{\omega\} \)). Note that, for all other variables \( y \in (\text{Var}_p \cup \text{Var}_G) \setminus \text{Var}^\omega \), \( D_a^y = D_y \). Then, we use \( \text{Val}_p^a \) to represent the abstract valuations of variables in \( \text{Var}_p \), which is a mapping for each variable to its abstract domain. Let \( \text{Val}_p^a = \bigcup_{v \in \text{Var}_p} \text{Val}_v^a \). The abstract valuations of global variables is represented similarly as \( \text{Val}_G^a \). Accordingly, the abstract states of a process type \( p \) are represented as \( S_p^a \subseteq I_p \times \text{Val}_G^a \), where \( I_p \) if the set of local states in the transition system \( TS_p \) as before. The abstract initial \( p \)-state is given by \( S_{p,\text{in}}^a = (I_{p,\text{in}}, \text{Val}^a_{p,\text{in}}) \), where \( \text{Val}^a_{p,\text{in}} \) is an initial valuation of variables in \( p \) over abstract variable domain. Further, we set \( S_p^a = \bigcup_{p \in \mathcal{P}} S_p^a \).

Since the domain of variables in \( \text{Var}^\omega \) differs in the abstract execution as compared to the concrete execution, we are to establish a relation between valuation of variables in the concrete and abstract execution as follows. Let \( \mathcal{R} \) be a relation between valuation of variables in concrete and abstract domain: \( \mathcal{R} \subseteq (\text{Val}_G \times \text{Val}_p) \times (\text{Val}_G^a \times \text{Val}_p^a) \). For all \( g \in \text{Val}_G, f \in \text{Val}_p, g_a \in \text{Val}_G^a, f_a \in \text{Val}_p^a : (g, f) \mathcal{R}(g_a, f_a) \) iff

1. \( \forall v \in \text{Var}_G \setminus \text{Var}^\omega, g_a(v) = g(v) \).
2. \( \forall v \in \text{Var}_p \setminus \text{Var}^\omega, f_a(v) = f(v) \).
3. \( \forall v \in \text{Var}_G \cap \text{Var}^\omega, g_a(v) = g(v), \text{if} \ g(v) \in [0, \text{cut}_p) \); and \( g_a(v) = \omega \), otherwise.
4. \( \forall v \in \text{Var}_p \cap \text{Var}^\omega, f_a(v) = f(v), \text{if} \ f(v) \in [0, \text{cut}_p) \); and \( f_a(v) = \omega \), otherwise.

5.2 Soundness with Process-count Variables

We now refine the relation \( \simeq \subseteq \text{CFG} \times \text{CFG}_{\text{abs}} \) with respect to \( \mathcal{R} \) between concrete and abstract configurations as follows.

**Definition 8.** For all \( C_c = (v_c^0, M_c) \in \text{CFG} \) and \( C_a = (v_a^0, M_a) \in \text{CFG}_{\text{abs}}, C_c \simeq C_a \iff \forall p \in \mathcal{P}, \forall s_c = (l, v_c) \in S_p, \exists s_a = (l, v_a) \in S_p^a, \text{s.t.} (v_a^0, v_c) \mathcal{R}(v_a^0, v_a) \land M_a(s_a) \geq |M_c(s_c)| \).

We now prove that our abstract execution semantics is an over-approximation of the concrete execution semantics.

**Theorem 3.** Let \( \sigma \) be a possibly infinite sequence of actions that can be exhibited in the concrete execution of a system model \( S \) with initially \( N^c_p \in \mathbb{N} \) processes of type \( p \).
Then, \( \sigma \) can be exhibited in the abstract execution of \( \mathcal{S} \) with initially \( N_p^a \) processes of type \( p \), where either \( N_p^a = \omega \) or \( N_p^a \in \mathbb{N} \) s.t. \( N_p^a \geq N_p^c \).

**Proof.** In order to prove this theorem, we consider the following property. Recall that \( \rightarrow \) and \( \rightarrow_a \) denote the concrete and abstract transition relations respectively.

**Property 1:**
\[
\forall (C_c, \alpha, C'_c) \in \rightarrow, \forall C_a \in CFG_{abs}, C_c \simeq C_a \Rightarrow \exists (C_a, \alpha, C'_a) \in \rightarrow_a, \text{s.t. } C'_c \simeq C'_a.
\]

We prove the above property as follows. Let \( C_c = (v^c_s, M_c), C'_c = (v'^c_s, M'_c) \in CFG \), and \( C_a = (v^a_s, M_a) \in CFG_{abs} \), s.t. \( (C_c, \alpha, C'_c) \in \rightarrow \) and \( C_c \simeq C_a \). Suppose by executing \( \alpha \), a process \( o \) of type \( p \) is moved from state \( s_c = (l, v_c) \) to state \( s'_c = (l', v'_c) \). Hence, update\(_c\)\((s_c, M_c, \alpha, s'_c, M'_c)\) in Def. 3 holds.

Since \( C_c \simeq C_a \), by Def. 8, \( \exists s_a = (l, v_a) \in S^p_\mathcal{S}, \text{s.t. } \gamma, f) \mathcal{R}(g, f) \land M_a(s_a) \geq |M_c(s_c)|, \) where \( g \in Val_G, f \in Val_\mathcal{S}, f_a \in Val^a_G, f_a \in Val^c_p. \) Since \( \alpha \) is executable from \( s_c \), to show that \( \alpha \) is also executable from \( s_a \) in the abstract execution, we first need to show that \( v^a_s \) and \( v_a \) satisfy \( Pre_\alpha \). Since \( (v^a_s, v_a) \mathcal{R}(v^a_s, v_a) \), let \( x \) be a variable in the system, we consider the following cases:

1. If \( x \in Val_G \setminus Val^\omega \), then \( g_a(x) = g(x) \), and hence \( g_a(x) \) satisfies \( Pre_\alpha \). Similar argument applies to \( x \in Val_p \setminus Val^\omega \).

2. If \( x \in Val_G \cap Val^\omega \), then \( g_a(x) \geq g(x) \). Now, consider boolean expression \( B \equiv x Relop c \), where \( Relop \) is any relational operator and \( c \) is a constant. Here, we take the case where \( Relop \) is \( \leq \) as an example. Various other relational operators can be considered in a similar fashion. Since \( g(x) \leq c \) evaluates to \( true \), we consider the evaluation of \( g_a(x) \leq c \) as follows.
   - If \( g(x) \in [0, cut_p] \), then \( g_a(x) = g(x) \). Hence, \( g_a(x) \leq c \) evaluates to \( true \).
   - If \( g(x) \geq cut_p \), then \( g_a(x) = \omega \). Let \( g(x) = n_0 \in \mathbb{N} \). Since \( \omega \) represents a value greater than or equal to \( cut_p \), \( g_a(x) \) is possible to evaluate to \( n_0 \geq cut_p \).

Therefore, we always allow the possibility that \( g_a(x) \leq c \) evaluates to \( true \).

Hence, whenever \( g(x) \) satisfies \( Pre_\alpha \), \( g_a(x) \) satisfies \( Pre_\alpha \). Similar argument applies to \( x \in Val_p \setminus Val^\omega \).

Let \( C'_a = (v'^a_s, M'_a) \in CFG_{abs} \) be the resulting abstract configuration, such that a process moves to state \( s'_a = (l', v'_a) \in S^p_\mathcal{S} \) by executing \( \alpha \) in abstract execution. Consider the global and local variables. For a variable \( x \), let \( v_c \) and \( v'_c \) be the valuation of \( x \) before and after execution of \( \alpha \) in concrete execution, respectively. Their corresponding valuations in the abstract execution are \( v_a \) and \( v'_a \). If \( x \in Val_G \setminus Val^\omega \), then since \( v_c = v_a \) and the effect of \( \alpha \) on \( x \) in concrete and abstract executions are identical. Hence, we have \( v'_c = v'_a \). Similar result is obtained for \( Val_p \setminus Val^\omega \). If \( x \in Val^\omega \), since \( v_a \geq v_c \), by the operational semantics for abstract-count variables, we have \( v'_a \geq v'_c \). Hence, we can easily see that \( (v^a_s, v'_a) \mathcal{R}(v^a_s, v'_a) \).

Further, similar to the proof of Theorem 1 in Section 4, by the semantics of \( update_\alpha \) and \( update_\alpha \), we have \( M'_a(s_a) \geq |M'_a(s_c)| \) and \( M'_a(s'_a) \geq |M'_a(s'_c)| \). Therefore, \( C'_a \simeq C'_a \).

Property 1 establishes that \( \simeq \) is a simulation relation. To complete the proof of the main theorem, we only need to show that the initial configurations in the concrete and abstract execution semantics are related by \( \simeq \). This is indeed the case, and this concludes the proof. \( \square \)

Fig. 5. Example of using process-count variable

Note that under condition \(C_1\) and \(C_2\) (refer Page 12), \(S_p^a = S_p\) for all process type \(p\) and \(D_x^a = D_x\) for all variable \(x\). Hence, our abstraction is again exact. Theorem 2 and its proof in Section 4 also apply in this case.

5.3 Elimination of Spuriousness Caused by Process-Count Variables

In our modeling, process-count variables can be used as a global shared-variable or local variable that keeps track of the number of processes in a particular control state of a process type. The use of data abstraction, in particular, process-count variables, introduces extra spurious behaviors in the system. This is mainly due to the fact that a process-count variable and the actual number of processes that it keeps track of are both updated in a non-deterministic manner. A server-client example in Figure 5 demonstrates the issue. In this example, a Server informs all the connected Clients of its status, and the number of connected clients is maintained via Server’s local variable \(\text{abs\_Client\_l2}\). After one execution of send and receive actions, four global states can be generated (Figure 6). The global states in dotted box are spurious, since in these states, the process-count variable (\(\text{abs\_Client\_l2}\)) is unbounded while the actual number of processes in the corresponding state (\(l_2\)) is a concrete number less than \(\text{cut\_Client}\), or vise-versa.

To eliminate the spuriousness caused by using process-count variables, we require that a process-count variable to be associated with a control state whose number of processes it keeps track of. In PROMELA, to count the number of processes at local state \(l\) of a process type \(p\), we follow the naming convention \(\text{abs\_p\_l}\) for the associated process-count variable. Moreover, an internal variable (name it as \(\text{int\_p\_l}\)) is used to maintain the execution choice of \(\text{abs\_p\_l}\) (i.e., \(\omega - 1 = \omega \) or \(\omega - 1 = \text{cut}_p\)). During state space exploration, when control reaches an execution state \(s = (l, v_p)\) of process type \(p\) and an action \(\alpha \in \Sigma\) is enabled, a check is performed to make sure that \(M_{\alpha}(s)\) matches the value of \(\text{abs\_p\_l}\) (note that, the only possible reason for the two not matching is because the initial assignment
of abs\_p\_l does not equal to \( M_\alpha(s) \), and hence should be reported as an error); moreover, after the execution of \( \alpha \), \( M_\alpha(s) \) is updated following our abstract semantics but with the same execution choice as the update of abs\_p\_l. Consider the Server-Client example in Figure 5. The control state associated with process-count variable abs\_Client\_l2 is \( l_2 \) of process type Client. When abs\_Client\_l2 is updated as a post-condition of action \( \alpha_0 \), internal variable int\_Client\_l2 is updated; and when \( \alpha_2 \) is enabled from an execution state \( s = (l_2, v_{\text{Client}}) \), \( M_\alpha(s) \) is updated based on the value of int\_Client\_l2, which ensures that the spurious global states (the dotted boxes in Figure 6) are never reached.

To summarize, the use of process-count variables in a PROMELA model requires the following steps:

1. Identify and label the control states that associate with any process-count variables.
2. Declare process-count variable (either local or global) using naming convention abs\_p\_l, such that it counts the number of processes at control state (with label) \( l \) of process type \( p \).

6. VERIFICATION

We now elaborate our verification procedure outlined earlier in Figure 1. It proceeds on the abstract state representation discussed in the preceding.

6.1 Model Checking

We use linear-time temporal logic (LTL) [Manna and Pnueli 1991] for specifying the properties to be verified. This decision is influenced by our use of model checker SPIN [Holzmann 2003] for implementing our verification framework. SPIN uses LTL as a property specification language. Properties in LTL are specified using atomic-propositions, boolean-operators (¬, ∨, ∧), and temporal-operators (G, F, X, U, R).

As described earlier in Section 5, our system model may also contain process-count variables (denoted as \( V^\omega \)), such that a variable \( v \in V^\omega \) is used for counting processes...
of a given type, say \(p\), with its domain ranging over \([0,\text{cut}_p)\cup\{\omega}\). Then, for LTL property specification, we restrict the boolean expressions involving a global process-count variable \(v\) to be of the form \(v \; \text{Relop} \; c\), such that \(c \in [0,\text{cut}_p)\) and \(\text{Relop}\) is any relational operator. This restriction ensures deterministic evaluation of boolean expressions involving the process-count variables.

Since we use SPIN as our underlying implementation framework, we are able to take advantage of its model checking capabilities. SPIN performs on-the-fly (explicit) state-space construction, while trying to find a counterexample trace violating the property being verified. If such a trace cannot be found, it means that the property holds true in the given system model. Otherwise, a counterexample trace indicating property violation is reported by SPIN. Our abstract execution semantics allow us to verify a family of concrete systems as follows.

Suppose a LTL property \(\varphi\) is satisfied in our abstract verification with \(N^a_p\) processes of type \(p\), where \(N^a_p \in \mathbb{N} \cup \{\omega\}\). Then, from Theorem 1, \(\varphi\) is also satisfied by all concrete systems having \(N^c_p \leq N^a_p\) processes of type \(p\), where \(N^c_p \in \mathbb{N}\).

### 6.2 Spurious counter-example detection

Our abstract execution semantics is an over-approximation in terms of allowed execution traces. Thus, a counter-example trace obtained from model checking over the abstract state space may be spurious, i.e. it cannot be exhibited in any concrete system with a finite number of processes (less-than or equal-to the number of processes in the abstract execution for each process type). In the following, we present an approach for detecting spurious counter-examples in the absence of process-count variable, and discuss abstraction-refinement for eliminating them in the next section. The result also holds in the presence of process-count variable with spuriousness elimination introduced in section 5.3.

We now introduce some definitions on finite traces. Note that our spurious counterexample detection and abstraction-refinement work for finite as well as infinite counterexample traces. The notions we introduce now, will work on finite prefixes of counter-example traces obtained from model checking.

Let \(\sigma = \alpha_1\ldots\alpha_n \in \Sigma^c\) be a finite execution trace s.t., action \(\alpha_i\) is executed by a process moving from execution state \(s_i \in S_P\) to state \(s'_i \in S_P\). We set \(\text{src}(\alpha_i) = s_i\) and \(\text{dst}(\alpha_i) = s'_i\). For a state \(s \in S_P\), we define:

\[
\begin{align*}
\text{in}(s, \sigma) &= | \{i \mid \text{dst}(\alpha_i) = s, i \in [1,n]\} | \\
\text{out}(s, \sigma) &= | \{i \mid \text{src}(\alpha_i) = s, i \in [1,n]\} |
\end{align*}
\]

Here, \(\text{in}(s, \sigma)\) (\(\text{out}(s, \sigma)\)) gives the number of processes moving in to (out of) state \(s\) during the execution of \(\sigma\). We use \(\text{new}(s, \sigma)\) (\(\text{del}(s, \sigma)\)) to represent the number of processes that are created (deleted) during execution of \(\sigma\) such that, they start (terminate) their execution in state \(s\). For convenience, we also define the following terms: \(\text{enter}(s, \sigma) = \text{in}(s, \sigma) + \text{new}(s, \sigma)\), and \(\text{leave}(s, \sigma) = \text{out}(s, \sigma) + \text{del}(s, \sigma)\). Finally, we define predicate \(\text{valid}(s, \sigma)\) as:

\[
\text{init}(s) + \text{enter}(s, \sigma) - \text{leave}(s, \sigma) > 0 \quad (3)
\]

Further, for a given finite trace \(\sigma\) and a process type \(p\) we define the quantity \(n_{p,\sigma}\) as follows. We first determine \(\text{leave}(s^n_{in}, \sigma)\), the number of \(p\) processes that move out from...
the initial $p$-state $s_{in}^p \in S_p$ during the execution of $\sigma$. Then, we define
\[ n_{p,\sigma} = \min(N_p, \text{leave}(s_{in}^p, \sigma)) \tag{4} \]
where $N_p \in \mathbb{N} \cup \{\omega\}$ is the initial number of processes of type $p$ in the abstract verification run, i.e. $N_p = \text{init}(s_{in}^p)$. Note that $n_{p,\sigma} \in \mathbb{N}$. Let $Pre(\sigma)$ denote the set of all prefixes of $\sigma$ (excluding $\sigma$). We now consider two cases, based on whether a counter-example is finite or infinite.

**Case-A: $\sigma$ is finite.** Let $\sigma = \alpha_0 \ldots \alpha_n$ be a finite counter-example trace obtained from an abstract verification run s.t., action $\alpha_i$ is executed by a process moving from state $s_i \in S_p$ to state $s_i' \in S_p$, i.e. $\text{src}(\alpha_i) = s_i$ and $\text{dst}(\alpha_i) = s_i'$. We show that $\sigma$ is non-sporious $\iff \forall \gamma \in Pre(\sigma), \text{valid}(s_{i|\gamma}, \gamma)$ is true in abstract execution.

**Proof.** $A.1 \iff$: Assume that $\forall \gamma \in Pre(\sigma), \text{valid}(s_{i|\gamma}, \gamma)$ is true in the abstract execution. We now show $\sigma$ to be non-sporious, by showing that $\sigma$ can be exhibited in the concrete execution of a system where each process type $p$ initially has $n_{p,\sigma}$ processes. The proof proceeds by induction on the length of $\sigma$.

**Base case:** It holds trivially for $|\sigma| = 0$.

**Induction hypothesis:** Trace $\sigma_1 = \alpha_0 \ldots \alpha_{k-1}$ can be exhibited in a concrete execution with initially $n_{p,\sigma}$ number of $p$-processes. Further, for all $0 \leq i < k$, action $\alpha_i$ has the same source state $\text{src}(\alpha_i)$ and destination state $\text{dst}(\alpha_i)$ in both concrete and abstract execution.

**Inductive step:** We now consider execution of $\sigma_1 \cdot \alpha_k$. Since, $\sigma_1$ is a prefix of $\sigma$ and $\forall \gamma \in Pre(\sigma), \text{valid}(s_{i|\gamma}, \gamma)$ is true in the abstract execution, $\text{valid}(s_k, \sigma_1)$ also holds in the abstract execution. Here, $k = |\sigma_1|$ and $s_k$ is the state from which a process executes $\alpha_k$ in the abstract execution. Thus, $\text{init}(s_k) + \text{enter}(s_k, \sigma_1) - \text{leave}(s_k, \sigma_1) > 0$ in the abstract execution (see Eq. (3)). Note that, both $\text{leave}(s_k, \sigma_1)$ and $\text{enter}(s_k, \sigma_1)$ depend on the source and destination states of processes executing various actions in $\sigma_1$. Since $\sigma_1$ is also exhibited in concrete execution (from induction hypothesis), the value of these quantities in concrete execution will be the same as in the abstract execution. We now consider following two cases for execution of $\alpha_k$ in the concrete execution.

1. **If** $s_k \in S_p$ is not the initial $p$-state ($s_k \neq s_{in}^p$), then $\text{init}(s_k) = 0$ in both abstract and concrete executions. Since, $\text{valid}(s_k, \sigma_1)$ is true in the abstract execution, we get $\text{enter}(s_k, \sigma_1) > \text{leave}(s_k, \sigma_1)$, which will also hold in the concrete execution. Hence, there is at least one process in state $s_k$ in concrete execution (after $\sigma_1$) which can be chosen to execute $\alpha_k$.

2. **If** $s_k = s_{in}^p$ is the initial $p$-state, then in the concrete execution there will be initially $n_{p,\sigma} = \min(N_p, \text{leave}(s_k, \sigma))$ processes in state $s_k$. Since $\text{valid}(s_k, \sigma_1)$ holds true in the abstract execution, we get $\text{init}(s_k) = N_p + \text{enter}(s_k, \sigma_1) > \text{leave}(s_k, \sigma_1)$. Recall that $n_{p,\sigma} = \min(N_p, \text{leave}(s_k, \sigma))$, as we are considering the case $s_k = s_{in}^p$. If $n_{p,\sigma} = N_p$ in concrete execution, since values of $\text{enter}(s_k, \sigma_1)$ and $\text{leave}(s_k, \sigma_1)$ in concrete execution are same as in the abstract execution, $\text{valid}(s_k, \sigma_1)$ is also true in the concrete execution — a process can then be chosen from $s_k$ to execute $\alpha_k$ in concrete execution. Otherwise, $n_{p,\sigma} = \text{leave}(s_k, \sigma)$. Since in abstract execution $\alpha_k$ is executed by a process in state $s_k$ (after occurrence of $\sigma_1$), we have $\text{leave}(s_k, \sigma) \geq \text{leave}(s_k, \sigma_1) + 1$. Thus, in the concrete...
execution $\text{valid}(s_k, \sigma_1)$ also holds since, $\text{init}(s_k) (= \text{leave}(s_k, \sigma) \> \text{enter}(s_k, \sigma_1) \> \text{leave}(s_k, \sigma_1)$, and a process from state $s_k$ can be chosen to execute $\alpha_k$.

A.2 $\Rightarrow$: We show this by contradiction. Assume that $\sigma = \alpha_0 \ldots \alpha_n$ is non-spurious. Then $\sigma$ can be exhibited in a concrete execution with $N^c_p \leq N_p$ ($N^c_p \in \mathbb{N}$) number of processes of type $p$, s.t. $\text{src}(\alpha_i) = s_i$ and $\text{dst}(\alpha_i) = s'_i$. Now assume that there exists a $\gamma = \alpha_0 \ldots \alpha_{k-1} \in \text{Pre}(\sigma)$ such that for $j \in [0, k-1]$ $\text{src}(\alpha_j) = s_j$, $\text{dst}(\alpha_j) = s'_j$, and $\text{valid}(s_k, \gamma) (k = |\gamma|)$ is false. This implies $\text{init}(s_k) + \text{enter}(s_k, \gamma) \> \text{leave}(s_k, \gamma) \leq 0$ in the abstract execution. If $s_k = s^p_{in}$ is the initial state of a type $p$, then initially there are $N_p$ processes in state $s_k$ in the abstract execution (i.e. $\text{init}(s_k) = N_p$ in abstract execution). In concrete execution $\text{init}(s_k)$ will be equal to $N^c_p \leq N_p$. Otherwise, if $s_k$ is not an initial state of any process type, then initially there are zero processes in $s_k$ in both abstract and concrete executions (i.e. $\text{init}(s_k) = 0$).

Therefore, in either case, the value of $\text{init}(s_k)$ in concrete execution is less than or equal to that in abstract execution. Further, since both $\text{leave}(s_k, \gamma)$ and $\text{enter}(s_k, \gamma)$ depend on the source and destination states of processes executing various actions in $\gamma$, their value in concrete execution will be same as in the abstract execution. Hence, $\text{init}(s_k) + \text{enter}(s_k, \gamma) \> \text{leave}(s_k, \gamma) \leq 0$ in the concrete execution, and there can be no process in state $s_k$ after the occurrence of $\gamma$ that can be chosen to execute $\alpha_k$, which is a contradiction. \(\Box\)

Case-B: $\sigma$ is infinite. In this case, $\sigma$ is of the form $\sigma_{pr}(\sigma_{sx})^{\omega}$. Here $\sigma_{pr}$ and $\sigma_{sx}$ are finite action sequences s.t., $(\sigma_{sx})^{\omega}$ represents an unbounded repetition of $\sigma_{sx}$, and the abstract configurations before and after each iteration of $\sigma_{sx}$ are same in abstract execution. Let $S_{\sigma_{sx}} \subseteq S_P$ denote the execution states from/to which processes move during an iteration of $\sigma_{sx}$. Then, we show that: $\sigma$ is non-spurious $\iff$ (i) $\sigma_{pr} \sigma_{sx}$ is non-spurious, and (ii) $\forall s \in S_{\sigma_{sx}} \cdot \text{enter}(s, \sigma_{sx}) = \text{leave}(s, \sigma_{sx})$.

PROOF. B.1 $\iff$: Suppose conditions (i) and (ii) hold above. Let $\sigma' = \sigma_{pr} \sigma_{sx}$. From condition-(i) we get that $\sigma'$ can be exhibited in a concrete system. In fact, by reusing the arguments from Case-A.1 described earlier, we get that $\sigma'$ can be exhibited in a concrete system with initially $n_{p, \sigma'} \in \mathbb{N}$ processes for each process type $p$.

Further, condition-(ii) ensures that the number of processes residing in state $s \in S_{\sigma_{sx}}$ before and after each iteration of $\sigma_{sx}$ are same. Hence, $\sigma_{sx}$ can be repeated infinitely often in the concrete execution. This means $\sigma = \sigma_{pr}(\sigma_{sx})^{\omega}$ is also exhibited in a concrete execution with $n_{p, \sigma'}$ processes for each process type $p$.

B.2 $\Rightarrow$ : Assume that $\sigma$ is non-spurious. Then $\sigma_{pr} \sigma_{sx}$ is also non-spurious (i.e. condition (i) holds), and it can be exhibited in a concrete execution. We use contradiction to show that condition (ii) also holds. Assume that there exists a state $s' \in S_{\sigma_{sx}}$ such that $\text{enter}(s', \sigma_{sx}) \neq \text{leave}(s', \sigma_{sx})$. Consider the following two cases: (a) $\text{enter}(s', \sigma_{sx}) < \text{leave}(s', \sigma_{sx})$, and (b) $\text{enter}(s', \sigma_{sx}) > \text{leave}(s', \sigma_{sx})$.

Case (a) above implies that after each iteration of suffix $\sigma_{sx}$, the number of processes in state $s'$ will be strictly less than what it was before the occurrence of $\sigma_{sx}$. Hence, after a finite number of iterations of $\sigma_{sx}$ in concrete execution, the number of processes in $s'$ will become 0. Therefore, $\sigma_{sx}$ cannot iterate infinitely often.

Case (b) above implies that after each iteration of suffix $\sigma_{sx}$, the number of processes in state $s'$ will be strictly greater than what it was before the occurrence of $\sigma_{sx}$. Hence, the
number of processes in $s'$ will grow unboundedly as $\sigma_{sx}$ is repeated infinitely often. If $s'$ is a state of process type $p$, the number of processes in $s'$ is no greater than the total number of processes of type $p$. However, in a concrete execution, the total number of processes of all process types is bounded. Thus, $\sigma$ cannot occur in a concrete execution (i.e. it is spurious), which contradicts our assumption. \hfill \Box

6.3 Abstraction Refinement

We now discuss an abstraction-refinement approach for eliminating spurious counter-examples.

Finite counter-example. Let $\sigma = \alpha_0 \ldots \alpha_n$ be a finite spurious counter-example such that, action $\alpha_i$ is executed by a process moving from state $s_i \in S_P$ to state $s_i' \in S_P$ in the abstract verification, i.e. $\text{src}(\alpha_i) = s_i$ and $\text{dst}(\alpha_i) = s_i'$. Recall that, $\text{Pre}(\sigma)$ is the set of all execution prefixes of $\sigma$, excluding $\sigma$ itself. Since, $\sigma$ is spurious, there exists a prefix $\gamma \in \text{Pre}(\sigma)$ such that $\text{valid}(s_{|\gamma|}, \gamma)$ is false (see Section 6.2, Case-A). We determine the smallest prefix $\sigma_m = \alpha_0 \ldots \alpha_{k-1}$ such that, in abstract execution: (i) $\neg\text{valid}(s_k, \sigma_m)$, where $k = |\sigma_m|$, and (ii) $\forall \gamma \in \text{Pre}(\sigma_m) \cdot \text{valid}(s_{|\gamma|}, \gamma)$. Since, $\text{valid}(s_k, \sigma_m)$ is false, this implies $\text{init}(s_k) + \text{enter}(s_k, \sigma_m) - \text{leave}(s_k, \sigma_m) \leq 0$. Hence, after the occurrence of $\sigma_m$ in abstract execution there can be no processes in state $s_k$. However, $\alpha_k$ is executed by a process from $s_k$ after the occurrence of $\sigma_m$ in abstract execution – this is only possible, if process count in $s_k$ becomes unbounded (i.e. $\omega$) during execution of $\sigma_m$. Assuming $s_k$ is a state of process type $p$, its process count can become $\omega$ only if number of processes in $s_k$ becomes $\text{cut}_p$ (the cutoff number of $p$) during execution of $\sigma_m$. In order to prevent the process count in $s_k$ from becoming $\omega$ in abstract execution, we determine the maximum number of processes that can reside in $s_k$ during execution of $\sigma_m$, i.e. $\text{max}(s_k, \sigma_m) = \text{max}\{\text{init}(s_k) + \text{enter}(s_k, \gamma) - \text{leave}(s_k, \gamma) | \gamma \in \text{Pre}(\sigma_m)\}$. Consequently, we set $\text{cut}_p = \text{max}(s_k, \sigma_m) + 1$ to prevent the occurrence of spurious trace $\sigma$ in subsequent abstract verification runs.

For illustration, consider the system model with a single process type $p_1$ as shown in Figure 2 and the LTL property $\neg(\alpha_0 \land X \alpha_1 \land X \alpha_2)$, specifying that the trace $\alpha_0 \alpha_1 \alpha_2$ never occurs. As shown earlier in Section 2, with $\text{cut}_p = 1$, $\sigma$ can be exhibited in the abstract execution s.t., $\text{src}(\alpha_0) = (l_3, \epsilon)$, $\text{dst}(\alpha_0) = (l_1, \epsilon)$, $\text{src}(\alpha_1) = \text{src}(\alpha_2) = (l_1, \epsilon)$, $\text{dst}(\alpha_1) = (l_2, \epsilon)$ and $\text{dst}(\alpha_2) = (l_3, \epsilon)$. Our check finds $\sigma$ to be spurious, as there exists $\sigma_m = \alpha_0 \alpha_1$ s.t. $\text{valid}(s_{|\sigma_m|}, \sigma_m)$ is false, where $s_{|\sigma_m|} = s_2 = \text{src}(\alpha_2) = (l_1, \epsilon)$. This is because, during execution of $\sigma_m$, we have $\text{init}(s_2) = 0$ and $\text{enter}(s_2, \sigma_m) = \text{leave}(s_2, \sigma_m) = 1$. Considering all prefixes of $\sigma_m$, we can easily find that $\text{max}(s_2, \sigma_m) = 1$. Then, if $\text{cut}_p$ is set to 2, the execution sequence $\sigma$ can no longer be exhibited in the abstract execution.

Infinite counter-example. Here $\sigma = \sigma_{pr}(\sigma_{sx})^\omega$. From Case-B in Section 6.2, $\sigma$ is spurious if either–

(i) $\sigma_{pr}\sigma_{sx}$ is spurious. This case is similar to that of the finite spurious counter-example discussed in the preceding.

(ii) $\sigma_{pr}\sigma_{sx}$ is not spurious, but there exists a state $s$ belonging to some process type $p$, from which a $p$-process executes one of the actions appearing in $\sigma_{sx}$ s.t. $\text{enter}(s, \sigma_{sx}) \neq \text{leave}(s, \sigma_{sx})$ in abstract execution.

For case (ii), since suffix $\sigma_{sx}$ is repeated infinitely often in the abstract execution of $\sigma$, the abstract configuration, and hence, the process counts in state $s$ are the same during repeated execution of $\sigma_{sx}$ in $\sigma$. As $\text{enter}(s, \sigma_{sx}) \neq \text{leave}(s, \sigma_{sx})$, this is only possible if
the count of processes in $s$ is approximated to $\omega$ sometime during the repeated execution of $\sigma_{sx}$. We consider two sub-cases.

**(ii-a)** The process count in $s$ is $\omega$ at the beginning/end of every execution of $\sigma_{sx}$ (in the abstract execution of $\sigma$).

**(ii-b)** The process count in $s$ is a natural number $n_0$ at the beginning/end of every execution of $\sigma_{sx}$ (in the abstract execution of $\sigma$). However, it grows to $\omega$ during execution of $\sigma_{sx}$ (and shrinks back to $n_0$ before next execution of $\sigma_{sx}$).

For case (ii-a), the process count in $s$ is $\omega$ at the beginning of the first execution of $\sigma_{sx}$ while executing $\sigma = \sigma_{pr}(\sigma_{sx})^\omega$, that is, at the end of $\sigma_{pr}$ itself. Our abstraction refinement sets the cutoff number of process type $p$ to the maximum value of $1 + \text{init}(s) + \text{enter}(s, \gamma) - \text{leave}(s, \gamma)$, where $\gamma \in \{\sigma_{pr}\} \cup \text{Pre}(\sigma_{pr})$. This bounds the maximum number of processes in state $s$ after execution of $\sigma_{pr}$.

For case (ii-b), our abstraction refinement similarly prevents the process count from becoming $\omega$ in $s$ during the execution of $\sigma_{sx}$ in $\sigma$. Here we set the cutoff number of process type $p$ to $1 + \max\{n_0 + \text{enter}(s, \gamma) - \text{leave}(s, \gamma) | \gamma \in \text{Pre}(\sigma_{sx})\}$.

### 6.4 Deriving a finite-state system for a non-spurious counter-example

Finally we discuss the derivation of a system with finite number of processes that can exhibit a given non-spurious counter-example trace $\sigma$. Thus, trace $\sigma$ is obtained from our abstract verification with unbounded number of processes, and then shown to be non-spurious (as per our spuriousness check). We consider two cases.

**(i)** $\sigma$ is finite. Then from Section 6.2, Case-A.1, we know that $\sigma$ can be exhibited in a finite state system with initially $n_{p,\sigma} \in \mathbb{N}$ number of processes of type $p$. From Eqn. (4) page 19, when the number of processes of type $p$ is unbounded, $n_{p,\sigma}$ is equal to $\text{leave}(s_{p}^{|\omega|}, \sigma)$ — the number of processes exiting the initial state of $p$ while executing $\sigma$.

**(ii)** $\sigma$ is infinite and hence is of the form $\sigma_{pr} \cdot (\sigma_{sx})^\omega$. Let $\sigma' = \sigma_{pr}\sigma_{sx}$. Since $\sigma$ is non-spurious, from Section 6.2, Case-B.1, $\sigma$ can be exhibited in a finite state system with initially $n_{p,\sigma'} \in \mathbb{N}$ number of processes of type $p$.

### 7. IMPLEMENTATION

SPIN [Holzmann 2003; 1997] is a popular open-source linear-time temporal logic (LTL) model checker for software verification. In this section, we describe our modifications involving process abstractions to SPIN, and for convenience call the modified version as SPIN++.

#### 7.1 Abstract State Representation

In SPIN, the state of each active process in the system is maintained separately during verification. The information maintained corresponding to each process consists of its current control state and a valuation of its local variables. In addition, a unique process id is used to identify each process in the system.

We modify the default SPIN state representation by introducing abstraction over process identities in SPIN++, such that process instantiations of the same process-type (declared using keyword `proctype` in SPIN) are no longer distinguished based on their process ids. Moreover, we no longer maintain the state of each process separately. Instead, processes corresponding to the same process-type, say $p$, are grouped into partitions during execution. Each such partition is identified by a $p$-state in $S_p$, consisting of a control state...
State Storage and Matching. In SPIN, each system state in the current exploration graph is stored for state matching during verification. In the SPIN state representation, the order of processes is fixed for all the states, and comparison of any two states is done byte by byte, with time complexity linear in the size of a system state. Consider the example shown in Figure 7(a), where type $p$ has two actions $\alpha_1$ and $\alpha_2$, and no local variables (hence, $p$'s execution state is characterized by its local control state). Two processes $o_1$ and $o_2$ of type $p$ are created, and a sequence of actions $\sigma = \alpha_1 \alpha_1 \alpha_2$ occurs. This results in the generation of four global states as shown in Figure 7(b), with $V_i^G$ ($i \in [0, 4]$) representing the valuations of global variables. We assume that $\alpha_1, \alpha_2$ do not modify global variables.

However, with process abstraction in SPIN++, although the order of active process types in each system state is fixed, the order of partitions within a process type $p$ (representing $p$'s execution states, i.e. a subset of $S_p$ with non-zero processes) may vary. This occurs due to the addition or deletion of partitions, as processes move in or out of partitions. Therefore, to be able to use the default SPIN state matching algorithm, we first sort the partitions corresponding to each process type before storing them in the state vector. Consider the same example in Figure 7(a). The abstract system states visited during the execution of $\sigma$ are shown in Figure 7(c). Among the four abstract global states generated, two of them (namely, $AS_1$ and $AS_3$) differ only in the permutation of partitions of type $p$. This is due to the dynamic addition and deletion of partitions as illustrated. As shown, sorting the partitions in $AS_3$ results in state $AS_1$ and hence, $AS_3$ is not stored as a new state in the state space.

\[ A partition is deleted when its process count becomes zero. \]
7.2 Preservation of SPIN Optimizations

Optimization techniques in SPIN fall into two categories—(a) reducing the number of reachable system states that must be searched to verify properties (e.g., partial order reduction and statement merging), and (b) reducing the amount of memory needed to store each state (e.g., collapse compression and bitstate hashing).

Partial Order Reduction. The partial order reduction and statement merging techniques are based on the knowledge of dependency relations among different transitions in a system model. In SPIN [Holzmann 2003], to avoid any run-time overheads, these dependency relations are computed off-line, before a model checking run is initiated. In our case, we only modify the state representation in SPIN without affecting the syntax or semantics of other operations. Hence, the dependency relations, and consequently the partial order reduction and statement merging are preserved with process abstractions in SPIN++. For illustration, consider a system consisting of a global variable $g$ and a process type $P$ with local variable $x$ as shown in Figure 8(a). The state exploration graph for this example in SPIN++ with two instantiations of process type $P$ is shown in Figure 8(b). Note that, for any two instantiations of $P$, transitions labeled $x = 1$ and $g = g + 2$ are mutually independent, and their different inter-leavings would lead to the same system state. For example, in Figure 8(b) the two paths $S_1.S_2.S_4$ and $S_1.S_3.S_4$ between system states $S_1$ and $S_4$ are considered equivalent. Hence, with partial order reduction enabled in SPIN++, the dashed path $(S_1.S_2.S_4)$ in Figure 8(b) is not explored.

Collapse compression. In addition, SPIN++ can also take advantage of state compression techniques such as collapse compression and bit-state hashing. Collapse compression addresses the state space explosion problem by dividing a system state into several “components”. These “components” are then assigned a unique index number and stored separately. This technique tries to exploit the observation that most of the components of two distinct system states may be the same. When collapse compression is enabled in SPIN, the global data objects and each active process in a system state are identified as system components. For example, in Figure 7(c), the global state $S_1$ of original SPIN consists of three
components: value of global variables, state of \( o_1 \) and state of \( o_2 \). In SPIN++, we consider the following as system “components” in a global system state — value of global variables, and the count of processes in each local state of each process type. For example, for the abstract global state \( AS_1 \) in SPIN++ as shown in Figure 7(c), the “components” would be — global information, and partitions \( s_0 = (l_0, \epsilon), s_1 = (l_0, \epsilon) \) of type \( P \) (\( \epsilon \) denotes emptiness of local variables). In other words, each local state (with process count greater than 0) of a process type is considered as a system component in our state representation. This enables the designer to use SPIN’s collapse compression optimization on our abstract state space.

**Bitstate hashing.** In SPIN, each system state is represented as a sequence of bits (i.e., a bitvector). With bitstate hashing enabled, a hash table containing single bit entries is used to store the visited states information. Further, a parameter \( k \) is used such that, \( k \) independent hash functions are applied to a system state, with each function pointing to an entry in the hash table. Then, if all the \( k \) entries in the hash table corresponding to some state are found to be 1, it indicates that the state has already been visited. Otherwise, the state has not been visited and any of the corresponding \( k \) bits that are 0 are set to 1. In SPIN the default value of \( k \) is 2 and can be set to other values using runtime options. Since several system states can map to the same hashtable entry, state space search with bitstate hashing may not be exhaustive. Of course, any counter-examples found can still be used for debugging. In our tool SPIN++, we also allow the designer the flexibility of using bitstate hashing. The only change is in how the bitvector representation of a system state is constructed. As mentioned earlier, a system state in the abstract state space consists of (a) the state of global variables and (b) process counts for all local states of all process types (for those local states where the process count is greater than 0). This state representation gets converted into a bitvector. The rest of the state space traversal — applying hash function(s) to the bitvector, looking up the hashtable, and storing 0/1 in a hash table entry depending on whether the state is visited — remains unchanged, allowing the designer to use bitstate hashing if he/she wants to.

8. **EXPERIMENTS**

In this section, we first describe our restrictions on PROMELA for system specification, and on LTL properties for property specification. We then discuss various experimental results involving the use of SPIN++ for verification. All our experiments were done on a Pentium-IV 3 GHz machine with 2 GB of main memory. We have made our parameterized checker available from [http://www.comp.nus.edu.sg/~abhik/SPIN++].

8.1 **Restrictions**

Our proof method is applicable to verification of arbitrary LTL properties for any PROMELA model, subject to the following restrictions. Recall that PROMELA is the input language of the SPIN model checker [Holzmann 2003; 1997] which allows system modeling via concurrent processes communicating by shared variables and/or message passing.

**Restrictions on PROMELA model.** Below, we summarize our restrictions on model specifications described in PROMELA.

—Since we suppress the use of process ids in our abstraction, we disallow the use of special SPIN variables \_pid and \_last, which can refer to individual process ids. For the same reason, we avoid accessing or checking the value returned by a run statement (which
creates a process and returns the process id in PROMELA).

—Only channels of size 0 can be declared, i.e. communication via message passing is synchronous. In addition, we allow inter-process communication via shared variables.

Any PROMELA model satisfying these two restrictions can be verified in our parameterized verification framework. Thus, the user can now model parameterized systems using a rich and popular modeling language like PROMELA, rather than having to construct FSMs for each process type. Note that dynamic process creation and annihilation is allowed in our system model.

Restrictions on LTL property. Given a PROMELA model satisfying the above restrictions, we verify any LTL property with the following restrictions.

—Atomic propositions in the LTL property do not refer to process identifiers. For example we cannot have an atomic proposition of the form \( \text{pid} = 1 \) where \( \text{pid} \) is a local variable capturing process identifiers. This restriction stems from our count abstraction which does not keep track of process identifiers.

—Recall that our system model may also contain process-count variables (denoted as \( Var^\omega \)), such that a variable \( v \in Var^\omega \) is used for counting processes of a given type, say \( p \), with its domain ranging over \([0, cut_p) \cup \{\omega\}\). Then, for LTL property specification, we restrict the boolean expressions involving a process-count variable \( v_p \) (which counts processes of type \( p \)) to be of the form \( v_p \ Relop c \), such that \( c \in [0, cut_p) \) and \( Relop \) is any relational operator. This restriction ensures deterministic evaluation of boolean expressions involving the process-count variables.

8.2 Examples Modeled

For experiments, we modeled the following four examples. In Table I, we summarize the key statistics of the PROMELA models for each of these examples.

The first example is a weather update controller, which is an important component of the Center TRACON Automation System (CTAS) automation tools developed by NASA for controlling air-traffic in large airports [CTA]. It consists of a central controller (CM), a weather-control panel (WCP), and several Client processes. Clients first get connected to the CM. Subsequently, all connected clients are updated with the latest weather information from WCP via CM.

</table>
The second example models part of the Media Oriented Systems Transport (MOST) protocol [MOS], which is a networking standard designed for interconnecting various multimedia components in automobiles. The main components consist of a network-manager (NM) and several network-slaves (NS). We model the network management part of this protocol which ensures secure communication between various applications in the MOST network.

The third example is the Java-metalock [Agesen et al. 1999] protocol, a distributed algorithm ensuring mutually exclusive access to a shared object (S) among arbitrary number of Java Threads. A hand-off process (H) handles the race between the releasing thread and several threads waiting to acquire S. If the object S is not-busy (i.e., no thread currently owns it), then a requesting thread is immediately granted access to it. Otherwise, S is busy and the owner thread releases access of S to one of the requesting threads via the hand-off process.

As the final example, we modeled the cache coherence part of the IEEE Futurebus+ Protocol [IEEE Computer Society 1992], where we restrict our model to contain only a single bus segment with one shared-memory module and multiple caches.

8.3 Reachability Analysis

The initial set of experiments involved doing a reachability analysis for the examples modeled using both SPIN and SPIN++. The main aim of these experiments was to (i) compare the run-time and memory usage between SPIN and SPIN++, and (ii) experimentally evaluate the benefits of partial order reduction and collapse-compression optimizations in SPIN++. For each example we created several versions differing in number of processes.

The experimental results for state space exploration are shown graphically in Figure 9. As we can observe, SPIN++ clearly outperforms SPIN by a significant margin as the number of processes in the system increases. Moreover, with the increasing number of processes, while almost linear growth is observed for both run-time and memory usage for SPIN++, the growths are exponential in case of SPIN. The results with \( \omega \) number of processes using SPIN++ are also shown (the last entry in these graphs).

In Figure 10, we show the reduction in the number of states explored due to partial order reduction (POR) for MOST and Java Meta-lock protocols in SPIN++. We are able to take significant advantage of POR using SPIN++ on these two protocols. The results for CTAS and Futurebus+ are omitted here, as they do not exhibit a significant improvement with POR enabled. For CTAS, there is almost no concurrency among Client processes, and they interact with the controller in a synchronous manner one by one; for Futurebus+ protocol, most transitions involve modification of shared global variables (used for communication) and hence, are not independent.

Finally, with collapse compression enabled in SPIN++, we could verify larger models which would otherwise run out of memory (see Table II). For example, CTAS with 200 Clients and MOST with 700 Slaves cannot be explored without using collapse compression. Both these instances ran out of memory as indicated by O.M. In case of Futurebus+ protocol, we observe less memory reduction as compared with the other two protocols. This is because, its model contains no local variables and a process state only consists of a control location. Hence, no significant reduction can be obtained using collapse compression.

8.4 Verification of LTL properties

We verified our examples against some interesting LTL properties using SPIN++. Here, we consider one property for each example and present the verification results. The verification results for our examples appear in Table III.

For CTAS, the weather-panel (WCP) is disabled each time there is an interaction initiated between Clients and the central-controller (CM), and is enabled once the interaction is over. Hence, for CTAS we specify a liveness property: whenever WCP is disabled, it will eventually be enabled (property P1, Tab. III).

In case of MOST, we verify the property — whenever network-manager receives a valid registration message from any slave, its registry gets updated (property P2, Tab. III).

For the Java meta-lock protocol, we verify the invariant property that at most one thread can own a shared object at any point of time (property P3, Tab. III).

For Futurebus+, we verify the property — if a cache holds an exclusively-modified copy of data, then no other caches can hold an exclusively-unmodified copy of the same data (property P4, Tab. III).

As we can observe from Table III, all examples satisfied the respective properties with initially a concrete number of processes for various process types. For these experiments, the choice of cutoff number is not an issue — since the number of processes is fixed initially and there is no unbounded process creation in these examples. In other words, the process counts never become ω, thus avoiding any spurious behaviors during abstract verification.

For experiments with an unbounded (ω) number of processes for some process type, spurious counter-examples may be reported by abstract verification. During abstract verification, the CTAS and MOST protocols satisfied their respective properties, with a cutoff number 1. For Futurebus+ protocol, a finite counter-example of length 34 was obtained, with cutoff number 1. However, our spuriousness check procedure (see Sec. 6.2) found this counter-example to be spurious. Using our abstraction-refinement approach (see Sec. 6.3), we obtained a new cutoff number of 2 for process-type Cache. Subsequently, verification with an unbounded number of caches in Futurebus+ protocol also succeeded. For the Java meta-lock protocol also, verification of mutual exclusion of shared object access by unbounded number of threads succeeded.

9. RELATED WORK

Verification of parameterized systems is undecidable [Apt and Kozen 1986]. There are two possible remedies to this problem: either we look for restricted subsets of parameterized
systems for which the verification problem becomes decidable, or we look for sound but not necessarily complete methods.

The first approach tries to identify a restricted subset of parameterized systems and temporal properties, such that if a property holds for a system with up to a certain number of processes, then it holds for every number of processes in the system. Moreover, the verification for the reduced system can be accomplished by model checking. Systems that are verified with this approach include systems with a single controller and arbitrary number of user processes [German and Sistla 1992], rings with arbitrary number of processes communicating by passing tokens [Emerson and Namjoshi 2003; Emerson and Kahlon 2004], systems formed by composing an arbitrary number of identical processes in parallel [Ip and Dill 1999], and systems formed by unbounded processes of several process types where the communication mechanism between the processes is restricted to conjunctive / disjunctive transition guards [Emerson and Kahlon 2000].

The sound but incomplete approaches include methods based on synthesis of invisible invariant (e.g., [Fang et al. 2006]) which can be viewed as a combination of assertion synthesis techniques with abstraction for verification; methods based on network invariant (e.g., [Lesens et al. 1997]) that relies on the effectiveness of a generated invariant and the invariant refinement techniques; regular model checking [Jonsson and Saksena 2007; Kesten et al. 1997] that requires acceleration techniques. Compositional proof methods have been studied in [Basu and Ramakrishnan 2003], while explicit induction based proof methods for parameterized families have been discussed in [Roychoudhury and Ramakrishnan 2001].

Parameterized verification of extended system models having data variables with unbounded domains have been studied (e.g., see [Abdualla et al. 2007; Betin-Can et al. 2005]). In comparison, our focus has been to link up our work with a mature system modeling and verification tool (we have chosen SPIN for this purpose). We do not define a new modeling language, whatever features are supported in PROMELA can appear in our system models. This frees the user from learning a new modeling language or tool for parameterized system verification.

</table>

The works closest to ours are the methods based on counter abstraction (e.g., [Delzanno 2000; Pong and Dubois 1995; Pnueli et al. 2002]). These works also employ process count abstraction. The verification of safety properties is discussed in [Delzanno 2000], the verification of liveness properties is addressed in [Pnueli et al. 2002]. Unlike previous works which perform one run of verification in the abstract state space, we use abstraction refinement to gradually discover cutoff numbers. To the best of our knowledge, ours is the first work to use abstraction refinement for parameterized system verification.

Murphi is an explicit-state model checker with extensions to support parameterized system verification [Ip and Dill 1999]. However, parameterized verification in Murphi is restricted to systems where only one process type has unbounded number of processes. SPIN is also an explicit-state model checker, whose enhancements have been studied for combating state space explosion. Different techniques have been proposed to remedy state space explosion, including – compositional verification methods as studied in [Pasareanu and Giannakopoulou 2006], and Symmetric SPIN, a symmetry reduction package for PROMELA programs [Bosnacki et al. 2000]. These approaches are not applicable to parameterized verification of systems with unbounded number of processes.

Counter-example guided abstraction refinement has earlier been studied for verification of large finite-state or infinite-state systems [Clarke et al. 2003; Beyer et al. 2007; Chaki et al. 2003; Ball and Rajamani 2002]. A common thread among these works is that they abstract the domains of variables which appear in the program being verified. However, if the program being verified is infinite-state because of having infinitely many processes — it is not clear how to employ abstraction refinement methods. In this paper, we have developed an abstraction refinement method on the previously studied counter-abstraction [Delzanno 2000; Pnueli et al. 2002], and used it for parameterized system verification.

10. DISCUSSION

In this paper, we have presented a pragmatic approach for verifying parameterized systems — concurrent systems with large / unbounded number of behaviorally similar processes. Our checker modifies the verification engine of the popular model checker SPIN by introducing process count abstractions. Since we do not modify PROMELA, the input language of SPIN, there is no learning curve involved for users. We can detect spurious counter-examples (introduced by our abstraction) and eliminate them via abstraction-refinement. Thus abstraction refinement seeks to discover the cutoff number of processes to be kept track of, for each process type with unboundedly many processes. For a non-spurious counter-example trace, we can construct a finite-state system which exhibits the same trace. We have made our parameterized checker available from http://www.comp.nus.edu.sg/~abhik/SPIN++/

In future, we plan to augment our parameterized verifier with data-abstraction refinement methods, which have been implemented in sequential software verifiers such as BLAST [Beyer et al. 2007], MAGIC [Chaki et al. 2003] and SLAM [Ball and Rajamani 2002]. This will allow us to verify systems with unbounded number of similar processes, as well as data variables with unbounded domains.
