Abstract. In this work, we study an extension of the k-center facility location problem where centers are required to service a minimum of clients. This problem is motivated by requirements to balance the workload of centers while allowing each center to cater to a spread of clients. We study three variants of this problem, all of which are shown to be $\mathcal{NP}$-hard. In-approximation hardness and approximation algorithms with factors equal or close to the best lower bounds are provided. Generalizations, including vertex costs and vertex weights, are also studied.

1 Introduction

The k-center problem is a well-known facility location problem and can be described as follows: Given a complete undirected graph $G = (V, E)$, a metric $d : V \times V \to \mathbb{R}_+$ and a positive integer k, we seek a subset $U \subseteq V$ of at most k centers which minimizes the maximum distances from points in V to U. Formally, the objective function is given by:

$$\min_{U \subseteq V, |U| \leq k} \max_{v \in V} \min_{r \in U} d(v, r).$$

As a typical example, we may want to set up k service centers (e.g., police stations, fire stations, hospitals, polling centers) and minimize the maximum distances between each client and these centers. The problem is known to be $\mathcal{NP}$-hard [4].

A factor ρ-approximation algorithm for a minimization problem is a polynomial time algorithm which guarantees a solution within at most ρ times the optimal cost. For the k-center problem, Hochbaum and Shmoys presented a factor 2-approximation algorithm and proved that no factor better than 2 can be achieved unless $\mathcal{P} = \mathcal{NP}$ [5]. Approximation algorithms for other k-center problems where vertex costs are considered or when vertex weights are used have been extensively studied [3, 6, 11]. More recently, Bar-Ilan, Kortsarz and Peleg investigated an interesting generalization of capacitated k-center problem where the number of clients for each center was restricted to a service capacity limit or maximum load [1]. Their work was improved in recent work by Khuller and Sussmann [9]. On the other hand, to ensure backup centers are available for clients, Krumke developed a "fault tolerant" k-center problem, where the objective was to minimize maximum distances as before, but where each client is required to be covered by a minimum number of centers [10]. Approximation algorithms for these problems were improved and extended in [2] and [8].

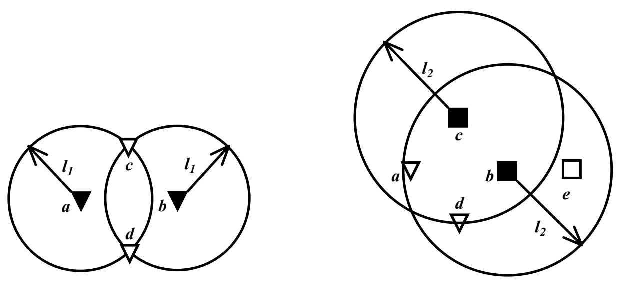
In these studies, no provision was made to ensure centers provide a minimum coverage of clients. In the fault tolerant problem, the client demand side of the problem is guaranteed coverage by a minimum number of centers (less than k), yet, on the supply side, there is no guarantee that each center services a minimum number of clients. In realistic applications however, such coverage is a common requirement. For example, in planning the location of hospitals, it would be expected that each hospital services a minimum number of neighborhoods. This would impose a balanced workload among hospitals and allow for economies of scale. Moreover, in cases when each center is equipped to provide a variety of services, a spread of clients covered is more likely to benefit service providers and clients alike. For example, where warehouses stock a variety of products, it would be beneficial if each services a spread of customers whose demands are more likely to include the range of products available. In this work, we address these provisions by extending the basic k-center problem to include a minimum coverage requirement. We allow coverage by different centers to overlap allowing clients to choose from a number of centers. In the problem, we minimize distances as in the basic k-center problem and require that every vertex in V is covered by one of the at most k selected centers in U. Further, each center in U must cover at least q vertices in V, where q is a non-negative integer, at most as large as $|V|$, which defines the minimum coverage for each center.

We call this a q-all-coverage k-center problem, with an objective function given by:

$$\min_{U\subseteq V,|U|\leq k} \max(\max_{v\in V} \min_{r\in U} d(v,r), \max_{r\in U} d_q(V,r)),$$

where $d_q(V,r)$ is the distance to r from its q^{th} closest vertex in V. Note that because $r \in V$, its closest vertex is r itself.

Figure 1(a) shows an instance of a 3-all-coverage 2-center problem, where each of the two centers, denoted by filled triangles, cover three vertices (including itself) within a distance l_1.



(a) k-center (b) k-supplier

Fig. 1. Instances of k-center and k-supplier problems

Further, two variations to this problem will be studied. The first is a q-coverage k-center problem, for which only vertices in $V - U$ are counted in the coverage of every center in U. Its objective function is:

$$\min_{U\subseteq V,|U|\leq k} \max(\max_{v\in V-U} \min_{r\in U} d(v,r), \max_{r\in U} d_q(V-U,r)),$$

where $d_q(V-U,r)$ is the distance of r from its q^{th} closest vertex in $V-U$. For example, in Figure 1(a), the two centers only satisfy the 2-coverage 2-center problem since the centers themselves are not counted in their own coverage.

The second is a q-coverage k-supplier problem for which V is partitioned into two disjoint subsets: S, a supplier set, and D, a demand set. The problem is then to find a subset U of at most

k centers in S to minimize distances where not only is every demand point in D covered by a center in U, but every center in U must cover at least q demands in D. Here, the objective function is:

$$\min_{U \subseteq S, |U| \leq k} \max(\max_{v \in D} \min_{r \in U} d(v, r), \max_{r \in U} d_q(D, r)),$$

where that $d_q(D, r)$ is the distance of r from its q^{th} closest demands in D.

Figure 1(b) gives an instance of the 2-coverage 2-supplier problem. Among three suppliers denoted by rectangles, the two filled ones are selected to be centers, each of which covers two demand points, distinguished by triangles, within a distance l_2.

Additionally, these three problems can be generalized by the inclusion of vertex costs and vertex weights, as has been done for the basic k-center problem. To include costs, we define a cost $c(v)$ for each vertex v in V where we now require $\sum_{r \in U} c(r) \leq k$. This cost generalization is useful, for example, in the case of building centers where the cost for centers can vary and when there is a limited budget as is the case in practice.

To extend the problems by including weights, we take $w(v)$ be the weight of each vertex v in V so that the weighted distance to vertex v from vertex u in V is $w(u, v) = d(u, v) \cdot w(v)$. For any vertex $v \in V$ and $X \subseteq V$, we let $w_q(X, v)$ to be the q^{th} closest weighted distance of v from the vertices in X. With this, the three variants can be generalized to weighted models by replacing distances d and d_q in the objective functions with the weighted distances w and w_q, respectively. Weighted distances can be useful, for example, when $1/w(v)$ is modelled to be the response speed of the center at vertex v, which then makes $w(u, v) = d(u, v).w(v)$ its response time.

Finally, by considering both vertex costs and vertex weights, we study the most general extensions for the three new problems.

Throughout this paper, OPT denotes the optimal value of the objective function. We assume that the complete graph $G = (V, E)$ is directed, where $V = \{v_1, ..., v_n\}$ and $E = V \times V = \{e_1, ..., e_m\}$ where $m = n^2$ where each vertex $v \in V$ has a self-loop $(v, v) \in E$ with distance $d(v, v) = 0$. For each edge $e_i \in E$, let $d(e_i)$ and $w(e_i)$ denote its distance and its weighted distance, respectively. A vertex v is said to *dominate* a vertex u, if and only if v is equivalent to u ($v = u$) or v is adjacent to u and we denote the number of vertices dominated by v in G by $deg^+(v)$. For each vertex v in the undirected graph H, $deg(v)$ is its *degree*, i.e. the number of adjacent edges including the possible self-loop (v, v), and for any undirected graph H, $I(H)$ denotes its *maximal independent set* [4], in which no two different vertices share an edge and no vertex outside $I(H)$ can be included while preserving its independence.

We present approximation algorithms for the three problems considered in this paper and their generalizations. Our methods extend from the threshold technique used for the basic k-center problem [6], and are designed to address the new minimum coverage constraints included.

The paper is organized as follows. In the next section, we summarize the main results of this work and, in subsequent sections, we provide approximation hardness and the approximation algorithms for the three problems: the q-all-coverage k-center problem, the q-coverage k-center problem, and the q-coverage k-supplier problem. For each problem considered, approximation algorithms are provided for the basic case and for its weight, cost, and weight plus cost generalizations. In section 6, we provide a conclusion.

2 Main Results

Our main results are summarized in Table 1. In the table, † indicates the best possible approximation factors have been achieved, which are shown to be 2, 2 and 3 for the three problems, respectively, unless $\mathcal{P} = \mathcal{NP}$. These optimal results include the basic cases of all the three problems considered, and the weight and the cost generalizations of the q-coverage k-supplier problem. Moreover, for the weight and the cost generalizations of the other two problems, approximation algorithms are provided with constant factors, all of which are close to their best possible approximation factor of 2. Especially, for the cost generalization of the q-all-coverage k-center problem indicated by ‡ in Table 1, a 3-approximation algorithm is achieved which matches the best known approximation factor for the cost generalization of the classical k-center problem [6].

Further to this, the approximation algorithms for the cost generalizations of the three problems can be extended to solve their weight plus cost generalizations. Let β denote the ratio between the maximum value and the minimum value of weights. Their approximation factors are consistent with those of their cost generalizations, which hold when $\beta = 1$.

Table 1. Summary of Approximation Factors

	Basic	Weights	Costs	Weights + Costs
q-All-Coverage K-center	$2^\dagger$	3	$3^\ddagger$	$2\beta + 1$
q-Coverage K-center	$2^\dagger$	4	4	$3\beta + 1$
q-Coverage K-supplier	$3^\dagger$	$3^\dagger$	$3^\dagger$	$2\beta + 1$

3 q-All-Coverage k-Center Problems

The following hardness result for the q-all-coverage k-center problem can be proved by extending the reduction from the *Domination Set* problem [4] used for the classical k-center problem [7].

Theorem 1. *Given any fixed non-negative integer q, there is no $(2 - \varepsilon)$-approximation algorithm for the q-all-coverage k-center problem, unless $\mathcal{NP} = \mathcal{P}$.*

Proof. See Appendix A.1. □

The best possible approximation factor of 2 can be achieved by Algorithm 1. We first sort edges in E by order of non-decreasing distances, i.e., $d(e_1) \leq d(e_2) \leq ... \leq d(e_m)$. Let $G_i = (V, E_i)$ where $E_i = \{e_1, ..., e_i\}$ for $1 \leq i \leq m$. Thus, if G_i has a set U of at most k vertices that dominate all vertices in G_i, and each vertex of U dominates at least q vertices (including itself) in G_i, then U provides at most k centers to the problem with at most $d(e_i)$ distance. Let i^* denote the smallest such index. So $d(e_i^*) = OPT$ is the optimal distance.

To find a lower bound for OPT, construct an undirected graph H_i. H_i contains an edge (u, v) where $u, v \in V$ might be equal if an only if there exists a vertex $r \in V$ with $deg^+(r) \geq q$ and both (u, r) and (v, r) are in G_i. It is clear that the self loop (v, v) remains in H_i for each $v \in V$, and that if $(v,u) \in G_i$ then $(v,u) \in H_i$ since (v,v) and (u,v) are in G_i. As any two vertices dominated by the same vertex in Q_i of G_i are adjacent in H_i, H_{i^*} satisfies the following:

1. for each vertex $v \in V$, $deg(v) \geq q$ in H_{i^*}, including its self-loop;
2. the size of its maximal independent set $|I(H_{i^*})| \leq k$.

Accordingly, suppose that the threshold j is the minimum index i leading H_i to satisfy the above two conditions, then we have $j \leq i^*$, which gives $d(e_j) \leq OPT$.

Finally, selecting vertices in the maximal independent set H_j, we have $|I(H_j)| \leq k$. So, centers in $I(H_j)$ dominate all vertices of V in H_j, and each $v \in I(H_j)$ dominates at least $deg(v) \geq q$ vertices (including itself) of V in H_j. By the triangle inequalities, we know $d(u,v) \leq 2d(e_j) \leq 2 \cdot OPT$, for every (u,v) in H_j. So the set U gives at most k centers with at most $2 \cdot OPT$ distance, which establishes the following theorem for the approximation factor of Algorithm 1.

Algorithm 1 (Basic q-All-Coverage k-Center)

1: Sort edges so that $d(e_1) \leq d(e_2) \leq ... \leq d(e_m)$, and construct $H_1, H_2, ..., H_m$;
2: Compute a maximal independent set, $I(H_i)$, in each graph H_i, where $1 \leq i \leq m$;
3: Find threshold j, denoting the smallest index i, such that $|I(H_i)| \leq k$, and for each $v \in V$, i$deg(v) \geq q$ in H_i;
4: Return $I(H_j)$.

Theorem 2. *Algorithm 1 gives an approximation factor of* 2 *for the q-all-coverage k-center problem.*

3.1 Any q with weights

From Algorithm 1, we have a 3-approximation Algorithm 2 for the weighted case of the q-all-coverage k-center problem. Firstly, sort edges by nondecreasing weighed distances, i.e., $w(e_1) \leq w(e_2) \leq ... \leq w(e_m)$ and let $G_i = (V, E_i)$ where $E_i = \{e_1, ..., e_i\}$. The graph H_i for G_i contains an edge (u,v) where $u, v \in V$ might be equal if an only if there exists a vertex r which has both (u,r) and (v,r) in G_i, which implies $w(u,r) \leq w(e_i)$ and $w(v,r) \leq w(e_i)$. To bound the optimum weighted distance (OPT), find the minimum index i and threshold j so that the degree of each vertex in H_i is at least q and the size of its maximal independent set is $|I(H_i)| \leq k$. This ensures $w(e_j) \leq OPT$. Finally, consider each vertex $v \in V$. Among all $u \in V$ with $w(v,u) \leq w(e_i)$, let $g_i(v)$ denote the vertex having the smallest weight, i.e., the least weighted neighbor of v in G_i. Shifting every $v \in I(H_j)$ to $g_j(v)$, we obtain the set U which guarantees an approximation factor of 3 given by the following theorem.

Theorem 3. *Algorithm 2 gives an approximation factor of* 3 *for the weighed q-all-coverage k-center problem.*

Proof. Firstly, by $|I(H_j)| \leq k$ and $U = \{g_j(v) | v \in I(H_j)\}$, we have $|U| \leq k$. Next, as shown in Figure 2, for any vertex $u \in V$, there must exist v in $I(H_j)$ with (u,v) in H_j, which gives a vertex $r \in V$ with both (u,r) and (v,r) in G_j. Hence, $w(u,r) \leq w(e_j)$ and $w(v,r) \leq w(e_j)$. Since $w(g_j(v)) \leq w(r)$ and $w(v, g_j(v)) \leq w(e_j)$, u is covered by $g_j(v) \in U$ within $w(u, g_j(v)) \leq$

Algorithm 2 (Weighed q-All-Coverage k-Center)

1: Sort edges so that $w(e_1) \leq w(e_2) \leq ... \leq w(e_m)$, and construct $H_1, H_2, ..., H_m$;
2: Compute a maximal independent set, $I(H_i)$, in each graph H_i, where $1 \leq i \leq m$;
3: Find threshold j, and denote the smallest index i, such that $|I(H_i)| \leq k$, and for each $v \in V$, $deg(v) \geq q$ in H_i;
4: Shift vertices in $I(H_j)$ to their least weighted neighbors in G_j, giving $U = \{g_j(v)|v \in I(H_j)\}$;
5: Return U;

$(d(u,r)+d(v,r)+d(v,g_j(v)))w(g_j(v)) \leq 3w(e_j)$. Furthermore, the degree of any vertex $v \in I(H_j)$ is at least q, which implies at least q vertices like u, equivalent or adjacent to v in H_j, can be covered by $g_j(v) \in U$ within $3w(e_j)$. Since $w(e_j) \leq OPT$, the approximation factor is 3 for Algorithm 2. □

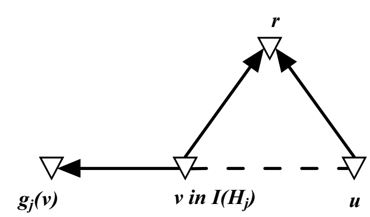


Fig. 2. Diagram for the proof of Theorem 3

3.2 Any q with weights and costs

We now give a $(2\beta + 1)$-approximation Algorithm 3 for the most general case where vertices have both weights and costs. If only cost is considered, a 3-approximation can be achieved where $\beta = 1$.

Algorithm 3 is similar to Algorithm 2 except that a new set U_i is constructed by shifting each $v \in I(H_i)$ to $s_i(v)$, where $s_i(v)$ is the vertex who has the lowest cost among all $u \in V$ with $w(v,u) \leq w(e_i)$. Hence $s_i(v)$ is called the cheapest neighbor of v in G_i and we take $U_i = \{s_i(v)|v \in I(H_i)\}$ and $c(U_i)$ to denote the total costs of vertices in U_i. Because no two vertices in $I(H_i)$ are dominated by a common vertex in G_i, the index i^* with $w(e_{i^*}) = OPT$ leads H_{i^*} to satisfy the following:

1. for each vertex $v \in V$, $deg(v) \geq q$ in H_{i^*}, including its self-loop;
2. $c(U_{i^*}) \leq k$.

Finding the threshold j to be the minimum index i which causes H_i to satisfy the above two conditions, we have $j \leq i^*$ and $w(e_j) \leq OPT$. Furthermore, we will prove that the U_j provides at most k cost centers ensuring an approximation factor of $(2\beta + 1)$ in the following.

Theorem 4. *Algorithm 3 gives an approximation factor of* $(2\beta+1)$ *for the weighed and cost q-all-coverage k-center problem.*

Proof. Because $c(U_j) \leq k$ and $w(e_j) \leq OPT$ have been shown, we need only show that the objective function distance given by U_j is at most $(2\beta + 1)w(e_j)$. On one hand, for any vertex $u \in V$, there exists a vertex $v \in I(H_j)$ adjacent to u in H_j. This implies there is a vertex $r \in V$ with both $w(u, r) \leq w(e_j)$ and $w(v, r) \leq w(e_j)$. Since $w(r) \leq \beta w(s_j(v))$ and $w(v, s_j(v)) \leq w(e_j)$, we know that v is covered by $s_j(v) \in U_j$ within $w(u, s_j(v)) \leq (d(u, r) + d(v, r) + d(v, s_j(v)))w(s_j(u)) \leq (2\beta + 1)w(e_j)$. On the other hand, because the degree of any vertex $u \in I(H_j)$ is at least q, there are at least q vertices like u, equivalent or adjacent to v in H_j, covered by $s_j(v) \in U_j$ within at most $(2\beta+1)w(e_j)$ weighed distance. Since $w(e_j) \leq OPT$, the approximation factor is $(2\beta+1)$ for Algorithm 3. □

Algorithm 3 (Weighed and Cost q-All-Coverage k-Center)

1: Sort edges so that $w(e_1) \leq w(e_2) \leq ... \leq w(e_m)$, and construct $H_1, H_2, ..., H_m$;
2: Compute a maximal independent set, $I(H_i)$, in each graph H_i, where $1 \leq i \leq m$;
3: Let $U_i = \{s_i(v) | v \in I(H_i)\}$, where $s_i(v)$ is the cheapest neighbor of v in G_i;
4: Find threshold j, denoting the smallest index i, such that $c(U_i) \leq k$, and for each vertex $v \in V$, $deg(v) \geq q$ in H_i;
5: Return U_j;

---

4 *q*-Coverage *k*-Center Problems

Compared with the q-all-coverage k-center problem, the q-coverage k-center problem has an additional stipulation: for each selected center v, the at least q vertices covered by v should be outside the set of selected centers.

To determine its hardness, we provide the following theorem, which can be shown by a modified reduction used for Theorem 1.

Theorem 5. *Given any fixed non-negative integer q, there is no $(2 - \varepsilon)$-approximation algorithm for the q-coverage k-center problem, unless $\mathcal{NP} = \mathcal{P}$.*

Proof. See Appendix A.2. □

The best possible approximation factor of 2 can be achieved for the q-coverage k-center problem by Algorithm 4 which is similar to Algorithm 1. The only difference is that the threshold j, found here, must cause the degree $deg(v)$ to be at least $q + 1$ in H_j instead of q for each vertex $v \in V$, since self-loops might exist but each center should be adjacent to q vertices other than itself. The approximation factor of 2 is proved by the following theorem.

Algorithm 4 (Basic q-Coverage k-Center)

1: Sort edges so that $d(e_1) \leq d(e_2) \leq ... \leq d(e_m)$, and construct $H_1, H_2, ..., H_m$;
2: Compute a maximal independent set, $I(H_i)$, in each graph H_i, where $1 \leq i \leq m$;
3: Find threshold j and denote the smallest index i, such that $|I(H_i)| \leq k$, and that for each $v \in V$, $deg(v) \geq q + 1$ in H_i;
4: Return $I(H_j)$.

Theorem 6. *Algorithm 4 gives an approximation factor of* 2 *for the q-coverage k-center problem.*

Proof. By the same analysis for Theorem 2, we know that $d(e_j) \leq OPT$, and that $I(H_j)$ provides at most k centers which cover all the vertices within at most $2d(e_j)$. Since each vertex $v \in I(H_j)$ is adjacent to at least q vertices other than itself in H_j, to prove its q-coverage within $2d(e_j)$ we need only show that no two vertices in $I(H_j)$ are adjacent to each other in H_j. This is obvious, since $I(H_j)$ is an independent set of H_j. Since $2d(e_j) \leq 2 \cdot OPT$, the approximation factor is 2. □

4.1 Any q with weights

The weighed case of the q-coverage k-center problem can be solved by Algorithm 5, which is more intricate than previous algorithms and can be described as follows.

First, after sorting the m edges, an undirected graph P_i, instead of H_i, is constructed from G_i for $1 \leq i \leq m$. The construction is as follows. Let Q_i be the subset of $v \in V$ with $deg^+(v) \geq q+1$. For any $u, v \in V$ where u and v might be equal, an edge (u, v) is in P_i if and only if there exits $r \in Q_i$ so that both (u, r) and (v, r) are in G_i. Consider the index i^* where $w(e_{i^*}) = OPT$. Because each selected center must dominate at least q vertices other than itself, and no two vertices in $I(P_{i^*})$ are dominated by the same vertex in G_{i^*}, we observe that:

1. each vertex of V is dominated by at least one vertex in Q_{i^*};
2. the size of $I(P_{i^*})$ must be at least as large as k, i.e. $|I(P_{i^*})| \leq k$.

Accordingly, define the threshold j to be the smallest index i, such that Q_i dominates all vertices of V, and $|I(P_i)| \leq k$. The two observations above imply $w(e_j) \leq OPT$.

Second, shift vertices in $I(P_j)$ as follows. For each vertex $v \in I(H_j)$, let $p(v)$ denote the smallest weighted vertex, among all $u \in Q_j$ with an edge (v, u) in G_j. This gives $U' = \{p(v) | v \in I(P_j)\}$.

Now, consider an undirected graph, $H' = (U', E')$, where, for any two vertices u and v in $I(P_j)$, an edge $(p(u), p(v)) \in E'$ if and only if either $(p(v), p(u))$ or $(p(u), p(v))$ is in G_j. Its maximal independent set, denoted by $I(H')$, can be obtained greedily by Algorithm 6. It is easily seen that for any vertex $u \in U' - I(H')$, there exists a vertex $v \in I(H')$ with $(u, v) \in E'$ and $w(v) \leq w(u)$, where v could be the vertex that marks u in Algorithm 6.

Now, we prove that $I(H')$ provides at most k centers ensuring an 4-approximation factor to establish the following theorem.

Theorem 7. *Algorithm 5 gives an approximation factor of* 4 *for the weighed q-coverage k-center problem.*

Proof. Noting $w(e_j) \leq OPT$ and $|I(H')| \leq |U'| \leq |I(P_j)| \leq k$, we need only prove the following two facts:

1. each $p(v) \in I(H')$ covers at least q vertices $u \in V - I(H')$ within $w(u, p(v)) \leq 4w(e_j)$, where $v \in I(P_j)$;
2. each $u \in V - I(H')$ is covered by a certain vertex $p(v) \in I(H')$ within $w(u, p(v)) \leq 4w(e_j)$, where $v \in I(P_j)$.

On one hand, consider each $p(v) \in I(H')$, where $v \in I(P_j)$. Because $I(H') \subseteq U' \subseteq Q_j$, we know $p(v) \in Q_j$, and so, there exist at least q vertices, other than $p(v)$, which are dominated by $p(v)$ in G_j. Moreover, each vertex u of these q vertices is not in $I(H')$, because otherwise, the edge

Algorithm 5 (Weighed q-Coverage k-Center)

Sort edges so that $w(e_1) \leq w(e_2) \leq ... \leq w(e_m)$;
For each $1 \leq i \leq m$, let $Q_i = \{v | deg^+(v) \geq q+1\}$;
Construct graphs, $P_1, P_2, ..., P_m$;
Compute a maximal independent set, $I(P_i)$ for each graph P_i where $1 \leq i \leq m$;
Find the threshold j, denote the smallest index i, such that Q_i dominates all vertices of V in G_i, and $|I(P_i)| \leq k$;
For each vertex $v \in I(P_j)$, let $p(v)$ denote the lowest weighed vertex among all vertices $u \in Q_j$ with an edge (v, u) in G_j;
Shift vertices in $I(P_j)$ by $U' = \{p(v) | v \in I(P_j)\}$;
Construct $H' = (U', E')$ from G_j, where for any two vertices u and v in $I(P_j)$, an edge $(p(u), p(v)) \in E'$ if and only if either $(p(v), p(u))$ or $(p(u), p(v))$ is in G_j;
Call Algorithm 6 to obtain $I(H')$, a maximal independent set of H', insuring that for any vertex $u \in U' - I(H')$, there exists a vertex $v \in I(H')$ with $(u, v) \in E'$ and $w(v) \leq w(u)$;
Return $I(H')$.

Algorithm 6 (Maximal Independent Set of $H' = (U', E')$ with Weights w)

$U \leftarrow \emptyset$;
while $U' \neq \emptyset$ **do**
  Choose the vertex v, which has the smallest weight $w(u)$ among all $u \in U'$;
  $U \leftarrow U + \{v\}$ and $U' \leftarrow U' - \{v\}$;
  Mark all the vertices $u \in U'$ adjacent to v, i.e $(u, v) \in E'$, by $U' \leftarrow U' - \{u\}$;
end while
Return U as the maximal independent set of H'.

$(u, p(v))$ in G_j implies an edge $(u, p(v))$ in H', contradicting to the independence of $I(H')$. Note that $w(u, p(v)) \leq w(e_j) \leq 4w(e_j)$. The fact 1 is proved.

On the other hand, consider each vertex $u \in V - I(H')$. As shown in Figure 3, because $I(P_j)$ is a maximal independent set of P_j, there exists a vertex $t_1 \in I(P_j)$ with an edge (u, t_1) in P_j. (Note that if u is in $I(P_j)$, a self loop (u, u) must be in P_j because all vertices of V are dominated by Q_j). Thus, we know that $p(t_1)$ is in H'. Since $I(H')$ is a maximal independent set of H', there exists a vertex $p(t_2) \in I(H')$ for $t_2 \in I(P_j)$, with $w(p(t_2)) \leq w(p(t_1))$ and an edge $(p(t_1), p(t_2))$ in H'. So $w(p(t_1), p(t_2)) \leq w(p(t_2), p(t_1))$, implying $(p(t_1), p(t_2))$ is in G_j. Because (u, t_1) is in P_j, there exits a vertex $a \in Q_j$ dominating both u and t_1 in G_j, leading $w(p(t_1)) \leq w(a)$. Noting that weighed distances of (u, a), (t_1, a), $(t_1, p(t_1))$, and $(p(t_1), p(t_2))$ are all at most $w(e_j)$, we have $w(u, p(t_2)) \leq (d(u, a) + d(t_1, a) + d(t_1, p(t_1)) + d(p(t_1), p(t_2)))w(p(t_2)) \leq 4w(e_j)$. This proves the fact 2 and completes the proof. □

4.2 Any q with weights and costs

As shown in Algorithm 7, the basic idea employed to solve the q-coverage k-center problem with weights and costs is to combine and modify Algorithm 3 and Algorithm 4. For the problem here, we construct $H_1, ..., H_m$ first and sort edges e_1, ..., e_m by their nondecreasing weighted distances.

However, to find the threshold j we need a new approach. For $1 \leq i \leq m$, an undirected graph

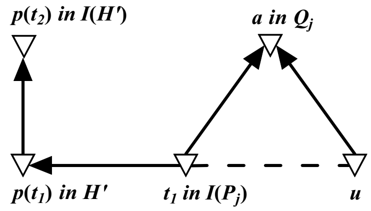

Fig. 3. Diagram of the proof for Theorem 7

H'_i is generated in the following manner: For any two vertices $u, v \in V$, the edge (u, v) is in H'_i, if and only if there exists a vertex $r \in V$, such that either (u, r) is in G_i and (v, r) is in H_i, or (v, r) is in G_i and (u, r) is in H_i. We then compute $I(H'_i)$, a maximal independent set of H'_i, and shift each vertex $v \in I(H'_i)$ to its lowest cost neighbor $s_i(v)$ in G_i; this forms the set $U'_i = \{s_i(v)|v \in I(H'_i)\}$.

Now, we find the threshold j, which is the minimal index i, giving $deg(v) \geq q+1$ in H_i for each vertex $v \in V$ and $c(U'_i) \leq k$, where $c(U'_i)$ denotes the total cost of vertices in U'_i. Observing that H'_i is a subgraph of H_i, we know $I(H'_i)$ is also an independent set of H_i. By similar arguments for Algorithm 3 and Algorithm 4, we derive $w(e_j) \leq OPT$.

To obtain the approximation factor, we prove that U'_j gives at most k cost centers within at most $(3\beta + 1) \cdot OPT$ weighed distance as follows.

Algorithm 7 (Weighed and Cost q-Coverage k-Center)

1: Sort edges so that $w(e_1) \leq w(e_2) \leq ... \leq w(e_m)$, and construct $H_1, H_2, ..., H_m$;
2: Construct $H'_1, H'_2, ..., H'_m$;
3: Compute a maximal independent set, $I(H'_i)$, in each graph H'_i, where $1 \leq i \leq m$;
4: Let $U'_i = \{s_i(v)|v \in I(H'_i)\}$, where $s_i(v)$ is the cheapest neighbor of v in G_i;
5: Find j, denoting the smallest index i, such that $c(U'_i) \leq k$, and that for each vertex $v \in V$, $deg(v) \geq q + 1$ in H_i;
6: Return U'_j;

Theorem 8. *Algorithm 7 gives an approximation factor of $3\beta + 1$ for the weighed and cost q-coverage k-center problem.*

Proof. We have obtained $w(e_j) \leq OPT$ and $c(U'_j) \leq k$. To show q-coverage for each $s_j(v) \in U'_j$ where $v \in I(H'_j)$, we estimate the weighed distance, $w(u, s_j(v))$, for any vertex u equivalent or adjacent to v in H_j but other than $s_j(v)$. As shown in Figure 4, since there exists a vertex r with $w(u, r) \leq w(e_j)$ and $w(v, r) \leq w(e_j)$, noting $w(v, s_j(v)) \leq w(e_j)$, we can obtain $w(u, s_j(v)) \leq (d(u, r) + d(v, r) + d(v, s_j(v)))w(s_j(v)) \leq (2\beta + 1)w(e_j) \leq (3\beta + 1) \cdot OPT$.

Moreover, the vertex u can not be in U'_j, because otherwise assuming $u = s_j(v')$ where v' is in $I(H'_j)$ but other than v. Since $(v', u) \in G_j$ and $(v, u) \in H_j$, we have $(v', v) \in H'_j$, leading contradiction to the independence of $I(H'_j)$.

Therefore, since $deg(v) \geq q + 1$ in H_j, we have that $V - U'_j$ contains at least q such vertices as

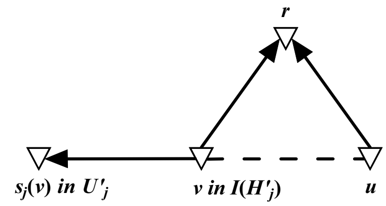

Fig. 4. Diagram for the proof of Theorem 8: the center $s_j(v) \in U'_j$ can cover any vertex u adjacent to $v \in I(H'_j)$ within $(3\beta + 1)w(e_j)$ weighted distance.

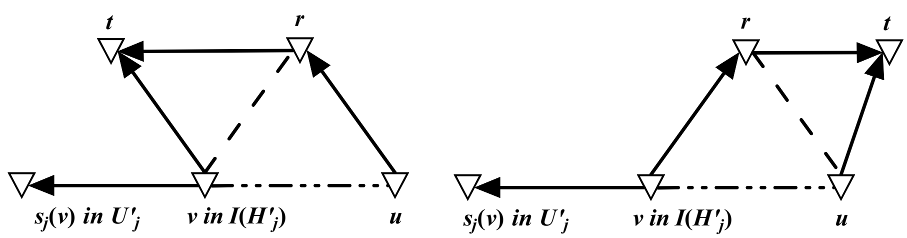
u, equivalent or adjacent to v in H_j, to be covered by $s_j(v)$ within $(3\beta+1) \cdot OPT$ weighed distance.

Now we prove that any vertex $u \in V - U'_j$ is covered by a certain vertex in U'_j within $(3\beta+1) \cdot OPT$ weighed distance. Because $I(H'_j)$ is a maximal independent set of H'_j, there exists a vertex $v \in I(H'_j)$ with $(u, v) \in H'_j$. This implies a vertex $r \in V$, having either $(u, r) \in G_j$ and $(v, r) \in H_j$, or $(v, r) \in G_j$ and $(u, r) \in H_j$. These two possible cases can both be proved to satisfy $w(u, s_j(v)) \leq (3\beta + 1) \cdot OPT$ as follows.



(a) when there exists a vertex r having $(u, r) \in G_j$ and $(v, r) \in H_j$

(b) when there exists a vertex r having $(v, r) \in G_j$ and $(u, r) \in H_j$

Fig. 5. Diagram for the proof of Theorem 8: two cases if the edge (u, v) is in H'_j

For the first case, if $(u, r) \in G_j$ and $(v, r) \in H_j$ as shown in Figure 5(a), then $w(u, r) \leq w(e_j)$, and there exists a vertex t with $w(v, t) \leq w(e_j)$ and $(r, t) \leq w(e_j)$. Noting $w(v, s_j(v)) \leq w(e_j)$, we can estimate the weighed distance $w(u, s_j(v))$ by $w(u, s_j(v)) \leq (d(u, r) + d(r, t) + d(v, t) + d(v, s_j(v)))w(s_j(v)) \leq (3\beta + 1)w(e_j) \leq (3\beta + 1) \cdot OPT$.

For the second case, if $(v, r) \in G_j$ and $(u, r) \in H_j$ as shown in Figure 5(a), then $w(v, r) \leq w(e_j)$, and there exists a vertex t with $w(u, t) \leq w(e_j)$ and $w(r, t) \leq w(e_j)$. Noting $w(v, s_j(v)) \leq w(e_j)$, we can also estimate the weighed distance $w(u, s_j(v))$ by $w(u, s_j(v)) \leq (d(u, t) + d(r, t) + d(v, r) + d(v, s_j(v)))w(s_j(v)) \leq (3\beta + 1)w(e_j) \leq (3\beta + 1) \cdot OPT$.

Noting that $v \in I(H'_j)$ implies $s_j(v) \in U'_j$, we obtain that U'_j gives at most k cost centers with at most $(3\beta + 1) \cdot OPT$ weighed distance. □

In addition, for the q-coverage k-center problem with cost only, Algorithm 7 has an approximation factor of 4 when $\beta = 1$.

5 q-Coverage k-Supplier Problems

The q-coverage k-supplier problem partitions the vertex set V into the supplier set S and the demand set D that are disjoint. Hence, at most k centers need be selected from S, to minimize the distance within which all the vertices in set D are covered by centers each of which must cover at least q suppliers in D. In order to determine its hardness, we present the following theorem which can be proved by a reduction of *Minimum Cover* problem [4].

Theorem 9. *Given any fixed non-negative integer q, there is no $(3-\varepsilon)$-approximation algorithm for the q-coverage k-center problem, unless $\mathcal{NP} = \mathcal{P}$.*

Proof. See Appendix A.3. □

The best possible approximation factor of 3 can be achieved for the q-coverage k-supplier problem, even for its weighed extension and its cost extension. In the rest of this section, we provide a 3-approximation algorithm for the weighed case first which is applicable for the basic case by specifying $w(u) = 1$ for each supplier $u \in S$. Then, we design a $(2\beta + 1)$-approximation algorithm for the weighed and cost case, which ensures a factor of 3 for the cost only case when $\beta = 1$.

5.1 Any q with weights

The approximation approach is formulated in Algorithm 8. As before, edges are sorted non-decreasingly, i.e., $w(e_1) \leq w(e_2) \leq ... \leq w(e_m)$. We have subgraphs G_1, G_2, ..., G_m, where $G_i = (V, E_i)$, $V = S \cup D$ and $E_i = \{e_1, ..., e_i\}$. To obtain the threshold index, a new graph L_i is constructed on the demand set D for each G_i as follows. For each two demands $u, v \in D$ where u may equal to v, an edge (u, v) is in L_i if an only if there exists a supplier $r \in S$ with both (u, r) and (v, r) in G_i. Hence, self-loops of all the vertices in V are still in L_i. Let $I(L_i)$ denote a maximal independent set of L_i. We find j to be the threshold index, which is the smallest index i, with $deg(v) \geq q$ in L_i for $v \in D$, and $|I(L_i)| \leq k$. Since i^*, the edge index of the optimal solution satisfies the above two conditions, and no two demands in $I(L_i)$ have edges from the same supplier in G_i for $1 \leq i \leq m$, we have $j \leq i^*$ leading to $w(e_j) \leq OPT$.

We shift each demand $v \in I(L_j)$ to its cheapest supplier $g_j(v)$ with the lowest weight among suppliers having an edge from v in G_j. This forms the center set $U = \{g_j(v) | v \in I(L_j)\}$, which provides at most k centers with at most a $3 \cdot OPT$ weighed distance. To see this, we prove the following theorem.

Theorem 10. *Algorithm 8 has an approximation factor of 3 for the weighed q-coverage k-center problem.*

Proof. Note $|U| \leq |I(L_j)| \leq k$ and $w(e_j) \leq OPT$. To obtain the approximation factor of 3, we need only show the following two facts:

1. each demand $u \in D$ is covered by a vertex in U within at most $3w(e_j)$;
2. each supplier $g_j(v) \in U$, where $v \in I(L_j)$, covers at least q demands in D within at most $3w(e_j)$.

Algorithm 8 (Weighed q-Coverage k-Supplier)

1: Sort edges so that $w(e_1) \leq w(e_2) \leq ... \leq w(e_m)$, and construct $L_1, L_2, ..., L_m$;
2: Compute a maximal independent set, $I(L_i)$, in each graph L_i, where $1 \leq i \leq m$;
3: Find j, denoting the smallest index i, such that $|I(L_i)| \leq k$, and that for each vertex $v \in D$, its degree $deg(v) \geq q$ in L_i;
4: For each demand $v \in I(L_j)$, let $g_j(v)$ denote the lowest weighted supplier among all suppliers $u \in S$ with an edge $(v, u) \in G_j$;
5: Let $U = \{g_j(v) | v \in I(L_j)\}$;
6: Return U.

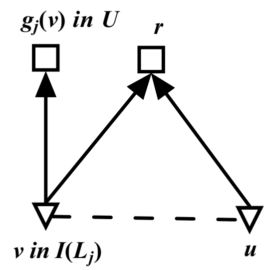


Fig. 6. Diagram for the proof of Theorem 10

To show fact 1, consider each demand $u \in D$. As shown in Figure 6, since $I(L_j)$ is a maximal independent set of L_j, there exists a vertex $v \in I(L_j)$ which has an edge (u, v) in L_j. This implies there is a supplier $r \in S$ with (u, r) and (v, r) in G_j. So both $w(u, r)$ and $w(v, r)$ are not more than $w(e_j)$. Noting $w(g_j(v)) \leq w(r)$ and $w(v, g_j(v)) \leq w(e_j)$, we can estimate the weighed distance from u to $g_j(v) \in U$ by $w(u, g_j(v)) \leq (d(u, r) + d(v, r) + d(v, g_j(v)))w(g_j(v)) \leq 3w(e_j)$.

The fact 2 is verified since for each supplier $g_j(v) \in U$ where $v \in I(L_j)$, the degree of v is at least q in L_j. Hence, at least q demands, equivalent or adjacent to v, are covered by $g_j(v)$ within $3w(e_j)$ by the same reasons for fact 1. By $w(e_j) \leq OPT$, the approximation factor is 3. □

5.2 Any q with weights and costs

Algorithm 9 presents a $(2\beta + 1)$-approximation algorithm for the q-coverage k-supplier problem with weights and costs. When $\beta = 1$, it ensures an approximation factor of 3 for the cost only case.

Compared with Algorithm 8, Algorithm 9 is changed as follows. After finding $I(L_i)$ for $1 \leq i \leq m$, we shift each demand $v \in I(L_i)$ to its cheapest supplier $s_i(v)$ with the lowest cost among all the suppliers having an edge from v in G_i. This forms $U_i = \{s_i(v) | v \in I(L_i)\}$. The threshold index j is the smallest index i, giving $deg(v) \geq q$ in L_i for $v \in D$ and the total cost of vertices in U_i, $c(U_i)$, is at most k. Since no two demands in $I(L_i)$ have edges from the same supplier in G_i for $1 \leq i \leq m$, we have $w(e_j) \leq OPT$.

Now, we prove that U_j have at most k cost centers within at most $(2\beta + 1) \cdot OPT$ weighed distance to establish the following theorem.

Theorem 11. *Algorithm 9 gives an approximation factor of* $(2\beta + 1)$ *for the weighed and cost* q*-coverage* k*-center problem.*

Algorithm 9 (Weighed q-Coverage k-Supplier)

1: Sort edges so that $w(e_1) \leq w(e_2) \leq ... \leq w(e_m)$, and construct $L_1, L_2, ..., L_m$;
2: Compute a maximal independent set, $I(L_i)$, in each graph L_i, where $1 \leq i \leq m$;
3: For each demand $v \in I(L_i)$, let $s_i(v)$ denote the cheapest cost supplier among all vertices $u \in S$ with edge $(v, u) \in G_i$;
4: Let $U_i = \{s_i(v) | v \in I(L_i)\}$ for $1 \leq i \leq m$;
5: Find j, denoting the smallest index i, such that $c(U_i) \leq k$, and that for each vertex $v \in D$, $deg(v) \geq q$ in L_i;
6: Return U_j.

Proof. By similar arguments in Theorem 10, the following two facts can be derived. On one hand, for each demander $u \in D$, there exists a vertex $v \in I(L_j)$ with $(u, v) \in L_j$. It is not hard to see that the weighed distance from u to $s_j(v) \in U_j$ is at most $(2\beta+1)w(e_j)$. On the other hand, each center $s_j(v) \in U_j$, where $v \in I(L_j)$ and $deg(v) \geq q$, can cover at least q vertices, which are equivalent or adjacent to v in L_j, within $(2\beta+1)w(e_j)$ weighed distance. Recalling that the total cost of U_j is at most k and that $w(e_j) \leq OPT$, we find that the approximation factor is $2\beta + 1$. □

6 Conclusion

We studied a new k-center problem which ensures minimum coverage of clients by centers. The problem is motivated by the need to balance services provided by centers while allowing centers to be utilized fully. We considered three variants of the problem. Besides in-approximation hardness, we provided approximation algorithms for the basic cases and generalized cases. The approximation factors found are close to or exactly at the best possible. Future work on this problem can include the consideration of the center capacities.

A Appendix of Some Proofs in Details

A.1 Proof of Theorem 1

Proof. Suppose there exists a $(2-\varepsilon)$-approximation algorithm, denoted by $\mathcal{W}_q$ for a certain fixed non-negative integer q. We will show that $\mathcal{W}_q$ can solve the *Dominating Set* [4], a well known $\mathcal{NP}$-complete problem, in polynomial time.

Dominating Set
INSTANCE: a graph $G = (V, E)$ and a positive integer $k \le |V|$.
QUESTION: is there a dominating set of size k or less for G, i.e., a subset $U \subseteq V$ with $|U| \le k$ such that for all $u \in V - U$ there is a $v \in U$ for which $(u, v) \in E$?

Given any instance of *Dominating Set*, consider the following instance of the q-all-coverage k-center problem for the fixed integer q. For each vertex $v \in V$, let $\Gamma_q(v) = \{\gamma_1(v), \gamma_2(v), ..., \gamma_q(v)\}$ and $V' = \bigcup_{v\in V} \Gamma_q(v)$. Construct a complete undirect graph $G' = (V', E')$. As shown in Figure 7, the distance on each edge $(u', v') \in E'$ is given as follows. If u' is equivalent to v', then $d(u', v') = 0$, otherwise,

$$d(u', v') = \begin{cases} 1 & \text{if both } u', v' \in \Gamma_q(v) \text{ for a certain } v \in V, \\ 1 & \text{if } u' \in \Gamma_q(u),\ v \in \Gamma_q(v) \text{ for } (u, v) \in E, \\ 2 & \text{otherwise.} \end{cases}$$

It is easy to verify that the distances satisfy the triangle inequality. We now prove that the algorithm $\mathcal{W}_q$ can decide whether G has a dominating set with at most k vertices of V.

On one hand, if G has a dominating set U with at most k vertices of V, let $U' = \{\gamma_1(v)|v \in U\}$, which contains at most k centers to cover all vertices in G' with distance 1. Noting that distance among any two vertices in $\Gamma_q(v)$ is 1 for $v \in V$, we can see that centers in U' satisfy the q-all-coverage as well. So the optimal distance is 1, and the $(2-\varepsilon)$-approximation algorithm $\mathcal{W}_q$ must return a solution with distance 1.

On the other hand, if $\mathcal{W}_q$ outputs a solution with distance 1, let U' denote the set of at most k centers. We construct the set $U = \{v|u \in \Gamma_q(v), u \in U', v \in V\}$, which can be easily verified to be a dominant set, with at most k vertices, of G.

Hence, Algorithm $\mathcal{W}_q$ can solve the $\mathcal{NP}$-complete *Dominating Set*, by checking whether or not its output is one, leading contradiction. □

A.2 Proof of Theorem 5

Proof. It can be proved by almost the same arguments for Theorem 1, except that we split each vertex $v \in V$ to $(q + 1)$ vertices in V' here, instead of to q ones before. In other words, we let $\Gamma_q(v) = \{\gamma_1(v), \gamma_2(v), ..., \gamma_q(v), \gamma_{q+1}(v)\}$ to insure the q-coverage, when reducing the q-coverage k-center problem from the the *Dominating Set.* □

A.3 Proof of Theorem 9

Proof. Suppose there exists such an $(3-\varepsilon)$-approximation algorithm, denoted by $\mathcal{W}_q$ for a certain fixed non-negative integer q. We will show that $\mathcal{W}_q$ can solve the *Minimum Cover* [4], a well known

$\mathcal{NP}$-complete problem, in polynomial time.

Minimum Cover

INSTANCE: a set $X = \{1, 2, ..., n\}$, a collection of subsets of X: $P = \{P_1, P_2, ..., P_m\}$, and a positive integer k.

QUESTION: Does P contain a cover for X of size k or less, i.e., a subset $P' \subseteq P$ with $|P'| \leq k$ such that every element of X belongs to at least one member of P'?

Given any instance of *Minimum Cover*, consider the following instance of the q-coverage k-supplier problem . Let $S = \{1, ..., m\}$ be the supplier set. Define $\Gamma_q = \{n+1, ..., n+q\}$ to be a set of q dummy demands. Let demander set $C = X \cup \Gamma_q$. For the graph $G = (V, E)$ where $V = S \cup C$, we define its edge distance as follows. For any two vertices u and v in V, if u equals to v then $d(u, v) = 0$, otherwise,

$$d(u,v) = \begin{cases} 1 & \text{if } v \in X,\ u \in S \text{ and } v \in P_u, \\ 3 & \text{if } v \in X,\ u \in S \text{ and } v \notin P_u, \\ 1 & \text{if } v \in \Gamma_q, \\ 2 & \text{otherwise.} \end{cases}$$

It is easy to verify that the distance d satisfies the triangle inequality. Figure 8 gives an example of this reduction. Now we are going to prove that algorithm $\mathcal{W}_q$ can decide whether X has a cover with at most k subsets in P.

On one hand, if X has a cover P' with at most k subsets in P, then P' will give at most k centers within 1 distance, because the dummy demands in Γ_q is 1 distance from each supplier in S, which makes each center in P' to satisfy the q-coverage. So, applying the $(3-\varepsilon)$-approximation algorithm $\mathcal{W}_q$ on $G = (V, E)$ must provide a solution with 1 distance, since the distance between any supplier and any demander is either 1 or 3.

On the other hand, if $\mathcal{W}_q$ outputs a solution with 1 distance, then let P' be the set of subsets P_u, for at most k suppliers u selected as centers in the solution. Because any demander $v \in X$ is covered by a selected center u within $d(u, v) = 1$, we know $v \in P_u$. By $P_u \in P'$, the set P' forms a cover of X with at most k size.

So the algorithm $\mathcal{W}_q$ can solve the $\mathcal{NP}$-complete *Minimum Cover*, by verifying whether or not its output is one, leading contradiction. □
