abstract

With the advent of multi-core architectures, worst case execution time (WCET) analysis has become an increasingly difficult problem. In this paper, we propose a unified WCET analysis framework for multi-core processors featuring both shared cache and shared bus. Compared to other previous works, our work differs by modeling the interaction of shared cache and shared bus with other basic micro-architectural components (e.g. pipeline and branch predictor). In addition, our framework does not assume a timing anomaly free multi-core architecture for computing the WCET. A detailed experiment methodology suggests that we can obtain reasonably tight WCET estimates in a wide range of benchmark programs.

0.1 Introduction

Hard real-time systems require absolute guarantees on program execution time. Worst case execution time (WCET) has therefore become an important problem to address. WCET of a program depends on the underlying hardware platform. Therefore, to obtain a safe upper bound on WCET, the underlying hardware need to be modeled. However, performance-enhancing micro-architectural features of a processor (e.g. cache, pipeline) make WCET analysis a very challenging task.

With the rapid growth of multi-core architectures, it is quite evident that the multi-core processors are soon going to be adopted for real-time system design. Although multi-core processors are aimed for improving performance, they introduce additional challenges in WCET analysis. Multi-core processors employ shared resources. Two meaningful examples of such shared resources are shared caches and shared buses. The presence of a shared cache requires the modeling of inter-core cache conflicts. On the other hand, the presence of a shared bus introduces variable bus access latency to accesses to shared cache and shared main memory. The delay introduced by shared cache conflict misses and shared bus accesses is propagated by different pipeline stages and affects the overall execution time of a program. WCET analysis is further complicated by a commonly known phenomenon called timing anomalies [Lundqvist and Stenström 1999]. In the presence of timing anomalies, a local worst case scenario may not lead to the WCET of the overall program. As an example, a cache hit rather than a cache miss may lead to the WCET of the entire program. Therefore, we cannot always assume a cache miss or maximum bus delay as the worst case scenario, as the assumptions are not just imprecise,
but they may also lead to an unsound WCET estimation. A few solutions have been proposed which model the shared cache and/or the shared bus (Yan and Zhang [2008]; Li et al. [2009]; Chattopadhyay et al. [2010]; Kelter et al. [2011]; Lv et al. [2010]) in isolation, but all of these previous solutions ignore the interactions of shared resources with important micro-architectural features such as pipelines and branch predictors.

In this paper, we propose a WCET analysis framework for multi-core platforms featuring both a shared cache and a shared bus. In contrast to previous work, our analysis can efficiently model the interaction of the shared cache and bus with different other micro-architectural features (e.g. pipeline, branch prediction). A few such meaningful interactions include the effect of shared cache conflict misses and shared bus delays on the pipeline, the effect of speculative execution on the shared cache etc. Moreover, our analysis framework does not rely on a timing-anomaly free architecture and gives a sound WCET estimate even in the presence of timing anomalies. In summary, the central contribution of this paper is to propose a unified analysis framework that features most of the basic micro-architectural components (pipeline, (shared) cache, branch prediction and shared bus) in a multi-core processor.

Our analysis framework deals with timing anomalies by representing the timing of each pipeline stage as an interval. The interval covers all possible latencies of the corresponding pipeline stage. The latency of a pipeline stage may depend on cache miss penalties and shared bus delays. On the other hand, cache and shared bus analysis interact with the pipeline stages to compute the possible latencies of a pipeline stage. Our analysis is context sensitive — it takes care of different procedure call contexts and different micro-architectural contexts (i.e. cache and bus) when computing the WCET of a single basic block. Finally, WCET of the entire program is formulated as an integer linear program (ILP). The formulated ILP can be solved by any commercial solver (e.g. CPLEX) to get the whole program’s WCET.

We have implemented our framework in an extended version of Chronos [Li et al. 2007], a freely available, open-source, single-core WCET analysis tool. To evaluate our approach, we have also extended a cycle-accurate simulator [Austin et al. 2002] with both shared cache and shared bus support. Our experiments with moderate to large size benchmarks from Gustafsson et al. [2010] show that we can obtain tight WCET estimates for most of the benchmarks in a wide range of micro-architectural configurations.
0.2 Related work

**WCET analysis in single core** Research in single-core WCET analysis has started a few decades ago. Initial works used only integer linear programming (ILP) for both micro-architectural modeling and path analysis [Li et al., 1999]. However, the work proposed in [Li et al., 1999] faces scalability problems due to the explosion in number of generated ILP constraints. In [Theiling et al., 2000], a novel approach has been proposed, which employs abstract interpretation for micro-architectural modeling and ILP for path analysis. Subsequently, an iterative fixed-point analysis has been proposed in [Li et al., 2006] for modeling advanced micro-architectural features such as out-of-order and superscalar pipelines. A different paper by the same set of authors [Li et al., 2005] has proposed an ILP-based modeling of branch predictors. Our baseline framework is built upon the techniques proposed in [Li et al., 2006, 2005].

**Timing analysis of shared cache** Although there has been a significant progress in single-core WCET analysis research, little has been done so far in WCET analysis for multi-cores. Multi-core processors employ shared resources (e.g. shared cache, shared bus), which gives rise to a new problem for modeling inter-core conflicts. A few solutions have already been proposed for analyzing a shared cache [Yan and Zhang, 2008; Li et al., 2009; Hardy et al., 2009]. All of these approaches extend the abstract interpretation based cache analysis proposed in [Theiling et al., 2000]. However, in contrast to our proposed framework, these approaches model the shared cache in isolation, assume a timing-anomaly-free architecture and ignore the interaction of shared cache with different other micro-architectural features (e.g. pipeline and branch prediction). A recent approach [Chattopadhyay and Roychoudhury, 2011] has enhanced the abstract interpretation based shared cache analysis with a gradual and controlled use of model checking. In [Chattopadhyay and Roychoudhury, 2011], abstract interpretation is used as a baseline analysis. Subsequently, a model checking pass is applied to improve the result generated by abstract interpretation. Since abstract interpretation is inherently path insensitive, it generates some spurious cache conflicts due to the presence of infeasible program paths. However, due to the path sensitive search process employed by a model checker, it eliminates certain *spurious* shared cache conflicts that can never be realized in any real execution. [Chattopadhyay and Roychoudhury, 2011] does not model the shared bus and any improvement generated by the approach proposed in [Chattopadhyay and Roychoudhury, 2011] will directly improve the precision of WCET prediction using our framework.
Timing analysis of shared bus  Shared bus analysis introduces several difficulties in accurately analyzing the variable bus delay. It has been shown in Wilhelm et al. [2009] that a time division multiple access (TDMA) scheme would be useful for WCET analysis due to its statically predictable nature. Subsequently, the analysis of TDMA based shared bus was introduced in Rosen et al. [2007]. In Rosen et al. [2007], it has been shown that a statement inside a loop may exhibit different bus delays in different iterations. Therefore, all loop iterations are virtually unrolled for accurately computing the bus delays of a memory reference inside loop. As loop unrolling is sometimes undesirable due to its inherent computational complexity, Chattopadhyay et al. [2010] proposed a TDMA bus analysis technique which analyzes the loop without unrolling it. However, Chattopadhyay et al. [2010] requires some fixed alignment cost for each loop iteration so that a particular memory reference inside some loop suffers exactly same bus delay in any iteration. The analysis proposed in Chattopadhyay et al. [2010] is fast, as it avoids loop unrolling, however imprecise due to the alignment cost added for each loop iteration. Finally, Kelter et al. [2011] proposes an efficient TDMA-based bus analysis technique which avoids full loop unrolling, but it is almost as precise as Rosen et al. [2007]. The analysis time in Kelter et al. [2011] significantly improves compared to Rosen et al. [2007]. However, none of the works (Rosen et al. [2007]; Chattopadhyay et al. [2010]; Kelter et al. [2011]) model the interaction of shared bus with pipeline and branch prediction. Additionally, Rosen et al. [2007] and Chattopadhyay et al. [2010] assume a timing-anomaly-free architecture. A recent approach Lv et al. [2010] has combined abstract interpretation and model checking for WCET analysis in multi-cores. The micro-architecture analyzed by Lv et al. [2010] contains a private cache for each core and it has a shared bus connecting all the cores to access main memory. The framework uses abstract interpretation (Theiling et al. [2000]) for analyzing the private cache and it uses model checking to analyze the shared bus. However, Lv et al. [2010] ignores the interaction of shared bus with pipeline and branch prediction. It is also unclear whether the proposed framework would remain scalable in the presence of shared cache and other micro-architectural features (e.g. pipeline).

Time predictable micro-architecture and execution model  To eliminate the problem of pessimism in multi-core WCET analysis, researchers have proposed predictable multi-core architectures Paolieri et al. [2009] and predictable execution models by code transformations Pellizzoni et al. [2011]. The work in Paolieri et al. [2009] proposes several micro-architectural
modifications (e.g. shared cache partitioning among cores, TDMA round robin bus) so that the existing WCET analysis methodologies for single cores can be adopted for analyzing the hard real-time software running on such system. On the other hand, [Pellizzoni et al. 2011] proposes compiler transformations to partition the original program into several time-predictable intervals. Each such interval is further partitioned into memory phase (where memory blocks are prefetched into cache) and execution phase (where the task does not suffer any last level cache miss and it does not generate any traffic to the shared bus). As a result, any other bus traffic scheduled during the execution phases of all other tasks does not suffer any additional delay due to the bus contention. We argue that the above mentioned approaches are orthogonal to the idea of this paper and our idea in this paper can be used to pinpoint the sources of overestimation in multi-core WCET analysis.

In summary, there has been little progress on multi-core WCET analysis by modeling the different micro-architectural components (e.g. shared cache, shared bus) in isolation. Our work differs from all previous works by proposing a unified framework, which is able to analyze the most basic micro-architectural components and their interactions in a multi-core processor.

0.3 Background

In this section, we introduce the basic background behind our WCET analysis framework. Our WCET analysis framework for multi-core is based on the pipeline modeling of [Li et al. 2006].

Pipeline modeling through execution graphs The central idea of pipeline modeling revolves around the concept of the execution graph [Li et al. 2006]. The execution graph is constructed for each basic block in the program control flow graph (CFG). For each instruction in the basic block, the corresponding execution graph contains a node for each of the pipeline stages. We assume a five stage pipeline — instruction fetch (IF), decode (ID), execution (EX), write back (WB) and commit (CM). Edges in the execution graph capture the dependencies among pipeline stages; either due to resource constraints (instruction fetch queue size, reorder buffer size etc.) or due to data dependency (read after write hazard). The timing of each node in the execution graph is represented by an interval, which covers all possible latencies suffered by the corresponding pipeline stage.

Figure 1 shows a snippet of assembly code and the corresponding execution graph. The example assumes a 2-way superscalar processor with 2-entry instruction fetch queue (IFQ) and
Figure 1: Execution graph for the example program in a 2-way superscalar processor with 2-entry instruction fetch queue and 4-entry reorder buffer. Solid edges show the dependency between pipeline stages, whereas the dotted edges show the contention relation.

4-entry reorder buffer (ROB). Since the processor is a 2-way superscalar, instruction I3 cannot be fetched before the fetch of I1 finishes. This explains the edge between IF nodes of I1 and I3. On the other hand, since IFQ size is 2, IF stage of I3 cannot start before ID stage of I1 finishes (edge between ID stage of I1 and IF stage of I3). Note that I3 is data dependent on I1 and similarly, I5 is data dependent on I4. Therefore, we have edges from WB stage of I1 to EX stage of I3 and also from WB stage of I4 to EX stage of I5. Finally, as ROB size is 4, I1 must be removed from ROB (i.e. committed) before I5 can be decoded. This explains the edge from CM stage of I1 to ID stage of I5.

A dotted edge in the execution graph (e.g. the edge between EX stage of I2 and I4) represents contention relation (i.e. a pair of instructions which may contend for the same functional unit). Since I2 and I4 may contend for the same functional unit (multiplier), they might delay each other due to contention. The pipeline analysis is iterative. Analysis starts without any timing information and assumes that all pairs of instructions which use same functional units and can coexist in the pipeline, may contend with each other. In the example, therefore, the analysis starts with \{(I1,I2), (I2,I4), (I1,I4), (I3,I5)\} in the contention relation. After one iteration, the timing information of each pipeline stage is obtained and the analysis may rule out some pairs from the contention relation if their timing intervals do not overlap. With this updated contention relation, the analysis is repeated and subsequently, a refined timing information is obtained for each pipeline stage. Analysis is terminated when no further elements can be removed from the contention relation. WCET of the code snippet is then given by the worst case completion time of the CM node for I5.
0.4 Overview of our analysis

Figure 2 gives an overview of our analysis framework. Each processor core is analyzed at a time by taking care of the inter-core conflicts generated by all other cores. Figure 2 shows the analysis flow for some program A running on a dedicated processor core. The overall analysis can broadly be classified into two separate phases: 1) micro-architectural modeling and 2) path analysis. In micro-architectural modeling, the timing behavior of different hardware components is analyzed (as shown by the big dotted box in Figure 2). We use abstract interpretation (AI) based cache analysis [Theiling et al. 2000] to categorize memory references as all-hit (AH) or all-miss (AM) in L1 and L2 cache. A memory reference is categorized AH (AM) if the resulting access is always a cache hit (miss). If a memory reference cannot be categorized as AH or AM, it is categorized as unclassified (NC). In the presence of a shared L2 cache, categorization of a memory reference may change from AH to NC due to the inter-core conflicts [Li et al. 2009]. Moreover, as shown in Figure 2, L1 and L2 cache analysis has to consider the effect of speculative execution when a branch instruction is mispredicted (refer to Section 0.7 for details). Similarly, the timing effects generated by the mispredicted instructions are also taken into account during the iterative pipeline modeling (refer to Li et al. [2006] for details). The shared bus analysis computes the bus context under which an instruction can execute. The outcome of cache analysis and shared bus analysis is used to compute the latency of different pipeline stages during the analysis of the pipeline (refer to Section 0.5 for details). Pipeline modeling is iterative and it finally computes the WCET of each basic block. WCET of the entire program is formulated as maximizing the objective function of a single integer linear program (ILP). WCETs of individual basic blocks are used to construct the objective function of the formulated ILP. The constraints of the ILP are generated from the structure of the program’s control flow graph (CFG), micro-architectural modeling (branch predictor and shared bus) and additional user-given constraints (e.g. loop bounds). The modeling of the branch predictor generates constraints to bound the execution count of mispredicted branches (for details refer to Li et al. [2005]). On the other hand, constraints generated for bus contexts bound the execution count of a basic block under different bus contexts (for details, refer to Section 0.6). Path analysis finds the longest feasible program path from the formulated ILP through implicit path enumeration (IPET). Any ILP solver (e.g. CPLEX) can be used for IPET and for deriving the whole program’s WCET.
System and application model  We assume a multi-core processor with each core having a private L1 cache. Additionally, multiple cores share a L2 cache. The extension of our framework for more than two levels of caches is straightforward. If a memory block is not found in L1 or L2 cache, it has to be fetched from the main memory. Any memory transaction to L2 cache or main memory has to go through a shared bus. For shared bus, we assume a TDMA-based round robin arbitration policy, where a fixed length bus slot is assigned to each core. We also assume fully separated caches and buses for instruction and data memory. Therefore, the data references do not interfere with the instruction references. In this work, we only model the effect of instruction caches. However, the data cache effects can be considered in a similar fashion. Since we consider only instruction caches, the cache miss penalty (computed from cache analysis) directly affects the instruction fetch (IF) stage of the pipeline. We do not consider self modifying code and therefore, we do not need to model the coherence traffic. Finally, we consider the LRU cache replacement policy and non-inclusive caches only. Later in Section 0.11, we shall extend our framework for FIFO cache replacement policy and we shall also discuss the extension of our framework for other cache replacement policies (e.g. PLRU) and other cache hierarchies (e.g. inclusive).

0.5 Interaction of shared resources with pipeline

Let us assume each node $i$ in the execution graph is annotated with the following timing parameters, which are computed iteratively:

- $earliest[t_{ready}^i], earliest[t_{start}^i], earliest[t_{finish}^i]$ : Earliest ready, earliest start and earli-
est finish time of node $i$, respectively.

- $latest[t^r_{i\text{ready}}], latest[t^s_{i\text{start}}], latest[t^f_{i\text{finish}}]$ : Latest ready, latest start and latest finish time of node $i$, respectively.

For each pipeline stage $i$, $earliest[t^r_{i\text{ready}}]$ and $earliest[t^s_{i\text{start}}]$ are initialized to zero, whereas, $earliest[t^f_{i\text{finish}}]$ is initialized to the minimum latency suffered by the pipeline stage $i$. On the other hand, $latest[t^r_{i\text{ready}}], latest[t^s_{i\text{start}}]$ and $latest[t^f_{i\text{finish}}]$ are all initialized to $\infty$ for each pipeline stage $i$. The active time span of node $i$ can be captured by the following timing interval: $[earliest[t^r_{i\text{ready}}], latest[t^f_{i\text{finish}}]]$. Therefore, each node of the execution graph is initialized with a timing interval $[0, \infty]$.

Pipeline modeling is iterative. The iterative analysis starts with the coarse interval $[0, \infty]$ for each node and subsequently, the interval is tightened in each iteration. The computation of a precise interval takes into account the analysis result of caches and shared bus. The iterative analysis eliminates certain infeasible contention among the pipeline stages in each iteration, thereby leading to a tighter timing interval after each iteration. The iterative analysis starts with a contention relation. Such a contention relation contains pairs of instructions which may potentially delay each other due to contention. Initially, all possible pairs of instructions are included in the contention relation and after each iteration, pairs of instructions whose timing intervals do not overlap, are removed from this relation. If the contention relation does not change in some iteration, the iterative analysis terminates. Since the number of instructions in a basic block is finite, the contention relation contains a finite number of elements and in each iteration, at least one element is removed from the relation. Therefore, this analysis is guaranteed to terminate. Moreover, if the contention relation does not change, the timing interval of each node reaches a fixed-point after the analysis terminates. In the following, we shall discuss how the presence of a shared cache and a shared bus affects the timing information of different pipeline stages.

### 0.5.1 Interaction of shared cache with pipeline

Let us assume $CHMC^L_1$ ($CHMC^L_2$) denotes the AH/AM/NC cache hit-miss classification of an IF node $i$ in L1 (shared L2) cache. Further assume that $E_i$ denotes the possible latencies
of an IF node $i$ without considering any shared bus delay. $E_i$ can be defined as follows:

$$E_i = \begin{cases} 
1, & \text{if } CHMC_i^{L1} = AH; \\
LAT_i^{L1} + 1, & \text{if } CHMC_i^{L1} = AM \land CHMC_i^{L2} = AH; \\
LAT_i^{L1} + LAT_i^{L2} + 1, & \text{if } CHMC_i^{L1} = AM \land CHMC_i^{L2} = AM; \\
[LAT_i^{L1} + LAT_i^{L1} + LAT_i^{L2} + 1], & \text{if } CHMC_i^{L1} = AM \land CHMC_i^{L2} = NC; \\
[1, LAT_i^{L1} + 1], & \text{if } CHMC_i^{L1} = NC \land CHMC_i^{L2} = AH; \\
[1, LAT_i^{L1} + LAT_i^{L2} + 1], & \text{otherwise.}
\end{cases}$$

(1)

where $LAT_i^{L1}$ and $LAT_i^{L2}$ represent the fixed L1 and L2 cache miss latencies respectively. Note that the interval-based representation captures the possibilities of both a cache hit and a cache miss in case of an NC categorized cache access. Therefore, the computation of $E_i$ can also deal with the architectures that exhibit timing anomalies.

### 0.5.2 Interaction of shared bus with pipeline

Let us assume that we have a total of $C$ cores and the TDMA-based round robin scheme assigns a slot length $S_l$ to each core. Therefore, the length of one complete round is $S_l C$. We begin with the following definitions which are used throughout the paper:

**Definition 0.5.1.** (TDMA offset) A TDMA offset at a particular time $T$ is defined as the relative distance of $T$ from the beginning of the last scheduled round. Therefore, at time $T$, the TDMA offset can be precisely defined as $T \mod S_l C$.

**Definition 0.5.2.** (Bus context) A Bus context for a particular execution graph node $i$ is defined as the set of TDMA offsets reaching/leaving the corresponding node. For each execution graph node $i$, we track the incoming bus context (denoted $O_i^{in}$) and the outgoing bus context (denoted $O_i^{out}$).

For a task executing in core $p$ (where $0 \leq p < C$), $\text{latest}[t_i^{finish}]$ and $\text{earliest}[t_i^{finish}]$ are computed for an IF execution graph node $i$ as follows:

$$\text{latest}[t_i^{finish}] = \text{latest}[t_i^{start}] + \max \text{lat}_p(O_i^{in}, E_i)$$

(2)

$$\text{earliest}[t_i^{finish}] = \text{earliest}[t_i^{start}] + \min \text{lat}_p(O_i^{out}, E_i)$$

(3)
Note that $\text{max}_{lat_p}$, $\text{min}_{lat_p}$ are not constants and depend on the incoming bus context ($O_{i}^{in}$) and the set of possible latencies of IF node $i$ ($E_i$) in the absence of a shared bus. $\text{max}_{lat_p}$ and $\text{min}_{lat_p}$ are defined as follows:

$$
\text{max}_{lat_p}(O_{i}^{in}, E_i) = \begin{cases} 
1, & \text{if } CHMC_{i}^{L1} = AH; \\
\max_{o \in O_{i}^{in}, t \in E_i} \Delta_p(o, t), & \text{otherwise.}
\end{cases}
$$

$$
\text{min}_{lat_p}(O_{i}^{in}, E_i) = \begin{cases} 
1, & \text{if } CHMC_{i}^{L1} \neq AM; \\
\min_{o \in O_{i}^{in}, t \in E_i} \Delta_p(o, t), & \text{otherwise.}
\end{cases}
$$

In the above, $E_i$ represents the set of possible latencies of an IF node $i$ in the absence of shared bus delay (refer to Equation 1). Given a TDMA offset $o$ and latency $t$ in the absence of shared bus delay, $\Delta_p(o, t)$ computes the total delay (including shared bus delay) faced by the IF stage of the pipeline. $\Delta_p(o, t)$ can be defined as follows (similar to Chattopadhyay et al. [2010] or Kelter et al. [2011]):

$$
\Delta_p(o, t) = \begin{cases} 
t, & \text{if } pS_l \leq o + t \leq (p + 1)S_l; \\
t + pS_l - o, & \text{if } o < pS_l; \\
t + (C + p)S_l - o, & \text{otherwise.}
\end{cases}
$$

In the following, we shall now show the computation of incoming and outgoing bus contexts (i.e. $O_{i}^{in}$ and $O_{i}^{out}$ respectively) for an execution graph node $i$.

**Computation of $O_{i}^{out}$ from $O_{i}^{in}$** The computation of $O_{i}^{out}$ depends on $O_{i}^{in}$, on the possible latencies of execution graph node $i$ (including shared bus delay) and on the contention suffered by the corresponding pipeline stage. In the modeled pipeline, inorder stages (i.e. IF, ID, WB and CM) do not suffer from contention. But the out-of-order stage (i.e. EX stage) may experience contention when it is ready to execute (i.e. operands are available) but cannot start execution due to the unavailability of a functional unit. Worst case contention period of an execution graph node $i$ can be denoted by the term $\text{latest}[t_{i}^{\text{start}}] - \text{latest}[t_{i}^{\text{ready}}]$. For best case computation, we conservatively assume the absence of contention. Therefore, for a particular core $p$ ($0 \leq p < C$),
we compute $O^\text{out}_i$ from the value of $O^\text{in}_i$ as follows:

$$O^\text{out}_i = \begin{cases} 
  u(O^\text{in}_i, E_i + [0, \text{latest}[t^\text{start}_i] - \text{latest}[t^\text{ready}_i]]), & \text{if } i = \text{EX}; \\
  u(O^\text{in}_i, \bigcup_{o \in O^\text{in}_i, t \in E_i} \Delta_p(o, t)), & \text{if } i = \text{IF}; \\
  u(O^\text{in}_i, E_i), & \text{otherwise}. 
\end{cases} \quad (7)$$

Here, $u$ denotes the update function on TDMA offset set with a set of possible latencies of node $i$ and is defined as follows:

$$u(O, X) = \bigcup_{o \in O, t \in X} \{(o + t) \mod S_i[C]\} \quad (8)$$

Note that $E_i + [0, \text{latest}[t^\text{start}_i] - \text{latest}[t^\text{ready}_i]]$ captures all possible latencies suffered by the execution graph node $i$, taking care of contentions as well. Therefore, $O^\text{out}_i$ captures all possible TDMA offsets exiting node $i$, when the same node is entered with bus context $O^\text{in}_i$. More precisely, assuming that $O^\text{in}_i$ represents an over-approximation of the incoming bus context at node $i$, the computation by Equation (7) ensures that $O^\text{out}_i$ represents an over-approximation of the outgoing bus context from node $i$.

**Computation of $O^\text{in}_i$**  The value of $O^\text{in}_i$ depends on the value of $O^\text{out}_j$, where $j$ is a predecessor of node $i$ in the execution graph. If $\text{pred}(i)$ denotes all the predecessors of node $i$, clearly, $\bigcup_{j \in \text{pred}(i)} O^\text{out}_j$ gives a sound approximation of $O^\text{in}_i$. However, it is important to observe that not all predecessors in the execution graph can propagate TDMA offsets to node $i$. Recall that the edges in the execution graph represent dependency (either due to resource constraints or due to true data dependences). Therefore, node $i$ in the execution graph can only start when all the nodes in $\text{pred}(i)$ have finished. Consequently, the TDMA offsets are propagated to node $i$ only from the predecessor $j$, which finishes immediately before $i$ is ready. Nevertheless, our static analyzer may not be able to compute a single predecessor that propagates TDMA offsets to node $i$. However, for two arbitrary execution graph nodes $j_1$ and $j_2$, if we can guarantee that $\text{earliest}[t^\text{finish}_{j_2}] > \text{latest}[t^\text{finish}_{j_1}]$, we can also guarantee that $j_2$ finishes later than $j_1$. The computation of $O^\text{in}_i$ captures this property:

$$O^\text{in}_i = \bigcup\{O^\text{out}_j \mid j \in \text{pred}(i) \land \text{earliest}[t^\text{finish}_{j}] \leq \text{latest}[t^\text{finish}_{j}]\} \quad (9)$$
where $p_{max}$ is a predecessor of $i$ such that $\text{latest}[t_{finish}^{p_{max}}] = \max_{j \in \text{pred}(i)} \text{latest}[t_{finish}^j]$. Therefore, $O_{i}^{in}$ captures all possible outgoing TDMA offsets from the predecessor nodes that are possibly finished latest. Given that the value of $O_{j}^{out}$ is an over-approximation of the outgoing bus context for each predecessor $j$ of $i$, Equation 9 gives an over-approximation of the incoming bus context at node $i$. Finally, Equation 7 and Equation 9 together ensure a sound computation of the bus contexts at the entry and exit of each execution graph node.

### 0.6 WCET computation under multiple bus contexts

#### 0.6.1 Execution context of a basic block

**Computing bus context without loops** In the previous section, we have discussed the pipeline modeling of a basic block $B$ in isolation. However, to correctly compute the execution time of $B$, we need to consider 1) contentions (for functional units) and data dependencies among instructions prior to $B$ and instructions in $B$; 2) contentions among instructions after $B$ and instructions in $B$. Set of instructions before (after) $B$ which directly affect the execution time of $B$ is called the prologue (epilogue) of $B$. $B$ may have multiple prologues and epilogues due to the presence of multiple program paths. However, the size of any prologue or epilogue is bounded by the total size of IFQ and ROB. To distinguish the execution contexts of a basic block $B$, execution graphs are constructed for each possible combination of prologues and epilogues of $B$. Each execution graph of $B$ contains the instructions from $B$ itself (called body) and the instructions from one possible prologue and epilogue. Assume we compute the incoming (outgoing) bus context $O_{i}^{in}(p, e)$ ($O_{i}^{out}(p, e)$) at body node $i$ for prologue $p$ and epilogue $e$ (using the technique described in Section 0.5). After we finish the analysis of $B$ for all possible combinations of prologues and epilogues, we compute an over-approximation of $O_{i}^{in}$ ($O_{i}^{out}$) by merge operation as follows:

$$O_{i}^{in} = \bigcup_{p, e} O_{i}^{in}(p, e) \quad (10)$$

$$O_{i}^{out} = \bigcup_{p, e} O_{i}^{out}(p, e) \quad (11)$$

Clearly, $O_{i}^{in}$ ($O_{i}^{out}$) captures an over-approximation of the bus context at the entry (exit) of node $i$, irrespective of any prologue or epilogue of $B$.  

13
Computing bus context in the presence of loops  In the presence of loops, a basic block can be executed with different bus contexts at different iterations of the loop. The bus contexts at different iterations depend on the set of instructions which can propagate TDMA offsets across loop iterations. For each loop $l$, we compute two sets of nodes — $\pi_{l}^{in}$ and $\pi_{l}^{out}$. $\pi_{l}^{in}$ are the set of pipeline stages which can propagate TDMA offsets across iterations, whereas, $\pi_{l}^{out}$ are the set of pipeline stages which could propagate TDMA offsets outside of the loop. Therefore, $\pi_{l}^{in}$ corresponds to the pipeline stages of instructions inside $l$ which resolve loop carried dependency (due to resource constraints, pipeline structural constraints or true data dependency). On the other hand, $\pi_{l}^{out}$ corresponds to the pipeline stages of instructions inside $l$ which resolve the dependency of instructions outside of $l$. Figure 3 demonstrates the $\pi_{l}^{out}$ and $\pi_{l}^{in}$ nodes for a sample execution graph. The bus context at the entry of all non-first loop iterations can be captured as $(O_{x1}^{in}, O_{x2}^{in}, \ldots, O_{xn}^{in})$ where $\pi_{l}^{in} = \{x1, x2, \ldots, xn\}$. The bus context at the first iteration is computed from the bus contexts of instructions prior to $l$ (using the technique described in Section 0.5). Finally, $O_{x_i}^{out}$ for any $x_i \in \pi_{l}^{out}$ can be responsible for affecting the execution time of any basic block outside of $l$. 

Figure 3: $\pi_{l}^{in}$ and $\pi_{l}^{out}$ nodes shown with the example of a sample execution graph. $\pi_{l}^{in}$ nodes propagate bus contexts across iterations, whereas, $\pi_{l}^{out}$ nodes propagate bus contexts outside of loop.
0.6.2 Bounding the execution count of a bus context

**Foundation**  As discussed in the preceding, a basic block inside some loop may execute under different bus contexts. For all non-first iterations, a loop \( l \) is entered with bus context \((O_{x_1}^{in}, O_{x_2}^{in}, \ldots, O_{x_n}^{in})\) where \( \{x_1, x_2, \ldots, x_n\} \) are the set of \( \pi_l^{in} \) nodes as described in Figure 3. These bus contexts are computed during an iterative analysis of the loop \( l \) (described below).

On the other hand, the bus context at the first iteration of \( l \) is a tuple of TDMA offsets propagated from outside of \( l \) to some pipeline stage inside \( l \). Note that the bus context at the first iteration of \( l \) is computed by following the general procedure as described in Section 0.5.

In this section, we shall show how the execution count of different bus contexts can be bounded by generating additional ILP constraints. These additional constraints are added to a global ILP formulation to find the WCET of the entire program. We begin with the following notations:

- \( \Omega_l \)  The set of all bus contexts that may reach loop \( l \) in any iteration.

- \( \Omega_l^s \)  The set of all bus contexts that may reach loop \( l \) at first iteration. Clearly, \( \Omega_l^s \subseteq \Omega_l \). Moreover, if \( l \) is contained inside some outer loop, \( l \) would be invoked more than once. As a result, \( \Omega_l^s \) may contain more than one element. Note that \( \Omega_l^s \) can be computed as a tuple of TDMA offsets propagated from outside of \( l \) to some pipeline stage inside \( l \). Therefore, \( \Omega_l^s \) can be computed during the procedure described in Section 0.5. If \( l \) is an inner loop, an element of \( \Omega_l^s \) is computed (as described in Section 0.5) for each analysis invocation of the loop immediately enclosing \( l \).

- \( G_l^s \)  For each \( s_0 \in \Omega_l^s \), we build a flow graph \( G_l^s = (V_l^s, F_l^s) \) where \( V_l^s \subseteq \Omega_l \). The graph \( G_l^s \) captures the transitions among different bus contexts across loop iterations. An edge \( f_{w_1 \rightarrow w_2} = (w_1, w_2) \in F_l^s \) exists (where \( w_1, w_2 \in \Omega_l \)) if and only if \( l \) can be entered with bus context \( w_1 \) at some iteration \( n \) and with bus context \( w_2 \) at iteration \( n+1 \). Note that \( G_l^s \) cannot be infinite, as we have only finitely few bus contexts that are the nodes of \( G_l^s \).

- \( M_l^w \)  Number of times the body of loop \( l \) is entered with bus context \( w \in \Omega_l \) in any iteration.

- \( M_l^{w_1 \rightarrow w_2} \)  Number of times \( l \) can be entered with bus context \( w_1 \) at some iteration \( n \) and with bus context \( w_2 \) at iteration \( n+1 \) (where \( w_1, w_2 \in \Omega_l \)). Clearly, if \( f_{w_1 \rightarrow w_2} \notin F_l^s \) for any flow
graph $G^s_l$, $M^w_1 \rightarrow w_2 = 0$.

**Construction of $G^s_l$**  For each loop $l$ and for each $s_0 \in \Omega^s_l$, we construct a flow graph $G^s_l$. Initially, $G^s_l$ contains a single node representing bus context $s_0 \in \Omega^s_l$. After analyzing all the basic blocks inside $l$ (using the technique described in Section 0.5), we may get a new bus context at some node $i \in \pi^m_l$ (recall that $\pi^m_l$ are the set of execution graph nodes that may propagate bus context across loop iterations). As a byproduct of this process, we also get the WCET of all basic blocks inside $l$ when the body of $l$ is entered with bus context $s_0$. Let us assume that for any $s \in \Omega_l \setminus \Omega^s_l$ and $i \in \pi^m_l$, $s(i)$ represents the bus context $O^m_l$. Suppose we get a new bus context $s_1 \in \Omega_l$ after analyzing the body of $l$ once. Therefore, we add an edge from $s_0$ to $s_1$ in $G^s_l$. We continue expanding $G^s_l$ until $s_n(i) \subseteq s_k(i)$ for all $i \in \pi^m_l$ and for some $1 \leq k \leq n - 1$ (where $s_n \in \Omega_l$ represents the bus context at the entry of $l$ after it is analyzed $n$ times). In this case, we finish the construction of $G^s_l$ by adding a backedge from $s_{n-1}$ to $s_k$. We also stop expanding $G^s_l$ if we have expanded as many times as the relative loop bound of $l$. Note that $G^s_l$ contains at least two nodes, as the bus context at first loop iteration is always distinguished from the bus contexts in any other loop iteration.

It is worth mentioning that the construction of $G^s_l$ is *much less computationally intensive* than a full unrolling of $l$. The bus context at the entry of $l$ quickly reaches a fixed-point and we can stop expanding $G^s_l$. In our experiments, we found that the number of nodes in $G^s_l$ never exceeds ten. For very small loop bounds (typically less than 5), the construction of $G^s_l$ continues till the loop bound. For larger loop bounds, most of the time, the construction of $G^s_l$ reaches the diverged bus context $[0, \ldots, S_l C - 1]$ quickly (in less than ten iterations). As a result, through a small node count in $G^s_l$, we are able to avoid the computationally intensive unrolling of every loop.

**Generating separate ILP constraints**  Using each flow graph $G^s_l$ for loop $l$, we generate ILP constraints to distinguish different bus contexts under which a basic block can be executed. In an abuse of notation, we shall use $w.i$ to denote that the basic block $i$ is reached with bus context $w.i$ when the immediately enclosing loop of $i$ is reached with bus context $w$ in any iteration. The following ILP constraints are generated to bound the value of $M^w_i$:

$$\forall w \in \Omega_l : \sum_{x \in \Omega_l} M^x_i \rightarrow w = M^w_i$$ (12)
∀w ∈ Ω_l : M_l^w - 1 ≤ \sum_{x \in Ω_l} M_{l}^{w \rightarrow x} \leq M_l^w \quad (13)

\sum_{w \in Ω_l} M_l^w = N_{l,h} \quad (14)

where N_{l,h} denotes the number of times the header of loop l is executed. Equations [12,13] generate standard flow constraints from each graph G_l^s, constructed for loop l. Special constraints need to be added for the bus contexts with which the loop is entered at the first iteration and at the last iteration. If w is a bus context with which loop l is entered at the last iteration, M_l^w is more than the execution count of outgoing flows (i.e. M_{l}^{w \rightarrow x}). Equation [13] takes this special case into consideration. On the other hand, Equation [14] bounds the aggregate execution count of all possible contexts w ∈ Ω_l with the total execution count of the loop header. Note that N_{l,h} will further be involved in defining the CFG structural constraints, which relate the execution count of a basic block with the execution count of its incoming and outgoing edges [2000]. Equations [12,14] do not ensure that whenever loop l is invoked, the loop must be executed at least once with some bus context in Ω_l^s. We add the following ILP constraints to ensure this:

∀w ∈ Ω_l^s : M_l^w \geq N_{l,h}^{w,h} \quad (15)

Here N_{l,h}^{w,h} denotes the number of times the header of loop l is executed with bus context w. The value of N_{l,h}^{w,h} is further bounded by the CFG structural constraints.

The constraints generated by Equations [12,15] are sufficient to derive the WCET of a basic block in the presence of non-nested loops. In the presence of nested loops, however, we need additional ILP constraints to relate the bus contexts at different loop nests. Assume that the loop l is enclosed by an outer loop l'. For each w' ∈ Ω_{l'}, we may get a different element s_0 ∈ Ω_l^s and consequently, a different G_l^s = (V_l^s, E_l^s) for loop l. Therefore, we have the following ILP constraints for each flow graph G_l^s:

∀G_l^s = (V_l^s, E_l^s) : \sum_{w \in V_l^s} M_l^w \leq bound_l * (\sum_{w' \in parent(G_l^s)} M_{l'}^{w'}) \quad (16)

where bound_l represents the relative loop bound of l and parent(G_l^s) denotes the set of bus contexts in Ω_{l'} for which the flow graph G_l^s is constructed at loop l. The left-hand side of
Equation 16 accumulates the execution count of all bus contexts in the flow graph $G_s^l$. The total execution count of all bus contexts in $V_s^l$ is bounded by $\text{bound}_l$, for each construction of $G_s^l$ (as $\text{bound}_l$ is the relative loop bound of $l$). Since $G_s^l$ is constructed $\sum_{w' \in \text{parent}(G_s^l)} M_{w'}$ times, the total execution count of all bus contexts in $V_s^l$ is bounded by the right hand side of Equation 16.

Finally, we need to bound the execution count of any basic block $i$ (immediately enclosed by loop $l$), with different bus contexts. We generate the following two constraints to bound this value:

$$\sum_{w \in \Omega_l} N_{w,i} = N_i$$  \hspace{1cm} (17)

$$\forall w \in \Omega_l : \ N_{w,i} \leq M_{w}^l$$  \hspace{1cm} (18)

where $N_i$ represents the total execution count of basic block $i$ and $N_{w,i}$ represents the execution count of basic block $i$ with bus context $w$. Equation 18 tells the fact that basic block $i$ can execute with bus context $w$ at some iteration of $l$ only if $l$ is reached with bus context $w$ at the same iteration (by definition). $N_i$ will be further constrained through the structure of program’s CFG, which we exclude in our discussion.

**Computing bus contexts at loop exit** To derive the WCET of the whole program, we need to estimate the bus context exiting a loop $l$ (say $O_l^{\text{exit}}$). A recently proposed work (Kelter et al. [2011]) has shown the computation of $O_l^{\text{exit}}$ without a full loop unrolling. In this paper, we use a similar technique as in Kelter et al. [2011] with one important difference: In Kelter et al. [2011], a single offset graph $G_{\text{off}}$ is maintained, which tracks the outgoing bus context from each loop iteration. Once $G_{\text{off}}$ got stabilized, a separate ILP formulation on $G_{\text{off}}$ derives the value of $O_l^{\text{exit}}$. In the presence of pipelined architectures, $O_{i}^{\text{out}}$ for any $i \in \pi_{l}^{\text{out}}$ could be responsible for propagating bus context outside of $l$ (refer to Figure 3). Therefore, a separate offset graph is maintained for each $i \in \pi_{l}^{\text{out}}$ (say $G_{i}^{\text{off}}$) and an ILP formulation for each $G_{i}^{\text{off}}$ can derive an estimation of the bus context exiting the loop (say $O_i^{\text{exit}}$). In Kelter et al. [2011], it has been proved that the computation of $O_i^{\text{exit}}$ is always an over-approximation (i.e. sound). Given that the value of each $O_i^{\text{out}}$ is sound, it is now straightforward to see that the computation of each $O_i^{\text{exit}}$ is also sound. For details of this analysis, readers are further referred to Kelter et al. [2011].

18
0.7 Effect of branch prediction

Presence of branch prediction introduces additional complexity in WCET computation. If a conditional branch is mispredicted, the timing of the mispredicted instructions need to be computed. Mispredicted instructions introduce additional conflicts in L1 and L2 cache which need to be modeled for a sound WCET computation. Similarly, branch misprediction will also affect the bus delay suffered by the subsequent instructions. In the following, we shall describe how our framework models the interaction of branch predictor on cache and bus. We assume that there could be at most one unresolved branch at a time. Therefore, the number of mispredicted instructions is bounded by the number of instructions till the next branch as well as the total size of instruction fetch queue and reorder buffer.

0.7.1 Effect on cache for speculative execution

Abstract-interpretation-based cache analysis produces a fixed point on abstract cache content at the entry (denoted as $ACS_{in}^i$) and at the exit (denoted as $ACS_{out}^i$) of each basic block $i$. If a basic block $i$ has multiple predecessors, output cache states of the predecessors are joined to produce the input cache state of basic block $i$. Consider an edge $j \rightarrow i$ in the program’s CFG. If $j \rightarrow i$ is an unconditional edge, computation of $ACS_{in}^i$ does not require any change. However, if $j \rightarrow i$ is a conditional edge, the condition could be correctly or incorrectly predicted during the execution. For a correct prediction, the cache state $ACS_{in}^i$ is still sound. On the other hand, for incorrect prediction, $ACS_{in}^i$ must be updated with the memory blocks accessed at the mispredicted path. We assume that there could be at most one unresolved branch at a time. Therefore, the number of mispredicted instructions is bounded by the number of instructions till the next branch as well as the total size of instruction fetch queue and reorder buffer. To maintain a safe cache state at the entry of each basic block $i$, we join the two cache states arising due to the correct and incorrect predictions of conditional edge $j \rightarrow i$. We demonstrate the entire scenario through an example in Figure 4. In Figure 4 we demonstrate the procedure for computing the abstract cache state at the entry of a basic block $i$. Basic block $i$ is conditionally reached from basic block $j$. To compute a safe cache content at the entry of basic block $i$, we combine two different possibilities —- one when the respective branch is correctly predicted (Figure 4(a)) and the other when the respective branch is incorrectly predicted (Figure 4(b)). The combination is performed through an abstract join operation, which depends on the type
Figure 4: (a) Computation of $acs^i_{in}$ when the edge $j \rightarrow i$ is correctly predicted, (b) Computation of $acs^i_{in}$ when the edge $j \rightarrow i$ is mispredicted, (c) A safe approximation of $acs^i_{in}$ by considering both correct and incorrect prediction of edge $j \rightarrow i$.

of analysis (must or may) being computed. A stabilization on the abstract cache contents at the entry and exit of each basic block is achieved through conventional fixed point analysis.

0.7.2 Effect on bus for speculative execution

Due to branch misprediction, some additional instructions might be fetched from the mispredicted path. As described in Section 0.6, an execution graph for each basic block $B$ contains a prologue (instructions before $B$ which directly affect the execution time of $B$). If the last instruction of the prologue is a conditional branch, the respective execution graph is augmented with the instructions along the mispredicted path (Li et al. [2006]). Since the propagation of bus context is entirely performed on the execution graph (as shown in Section 0.5), our shared bus analysis remains unchanged, except the fact that it works on an augmented execution graph (which contains instructions from the mispredicted path) in the presence of speculative execution.

0.7.3 Computing the number of mispredicted branches

In the presence of a branch predictor, each conditional edge $j \rightarrow i$ in the program CFG can be correctly or incorrectly predicted. Let us assume $E_{j \rightarrow i}$ denotes the total number of times control flow edge $j \rightarrow i$ is executed and $E_{j \rightarrow i}^c$ ($E_{j \rightarrow i}^m$) denotes the number of times the control flow edge $j \rightarrow i$ is executed due to correct (incorrect) branch prediction. Clearly, $E_{j \rightarrow i} = E_{j \rightarrow i}^c + E_{j \rightarrow i}^m$.

Value of $E_{j \rightarrow i}$ is further bounded by CFG structural constraints. On the other hand, values of $E_{j \rightarrow i}^c$ and $E_{j \rightarrow i}^m$ depend on the type of branch predictor. We use our prior work (Li et al. [2005]), where we have shown how to bound the values of $E_{j \rightarrow i}^c$ and $E_{j \rightarrow i}^m$ for history based
branch predictors. The constraints generated on $E^c_{j \rightarrow i}$ and $E^m_{j \rightarrow i}$ are as well captured in the global ILP formulation to compute the whole program WCET. We exclude the details of branch predictor modeling in this paper — interested readers are referred to Li et al. [2005].

### 0.8 WCET computation of an entire program

We compute the WCET of the entire program with $N$ basic blocks by using the following objective function:

$$\text{Maximize } T = \sum_{i=1}^{N} \sum_{j \rightarrow i} \sum_{w \in \Omega_i} t^{c,w}_{j \rightarrow i} \ast E^{c,w}_{j \rightarrow i} + t^{m,w}_{j \rightarrow i} \ast E^{m,w}_{j \rightarrow i}$$  \hspace{1cm} (19)$$

$\Omega_i$ denotes the set of all bus contexts under which basic block $i$ can execute. Basic block $i$ can be executed with different bus contexts. However, the number of elements in $\Omega_i$ is always bounded by the number of bus contexts entering the loop immediately enclosing $i$ (refer to Section 0.6).

$t^{c,w}_{j \rightarrow i}$ denotes the WCET of basic block $i$ when the basic block $i$ is reached from basic block $j$, the control flow edge $j \rightarrow i$ is correctly predicted and $i$ is reached with bus context $w \in \Omega_i$. Similarly, $t^{m,w}_{j \rightarrow i}$ denotes the WCET of basic block $i$ under the same bus context but when the control flow edge $j \rightarrow i$ was mispredicted. Note that both $t^{c,w}_{j \rightarrow i}$ and $t^{m,w}_{j \rightarrow i}$ are computed during the iterative pipeline modeling (with the modifications proposed in Section 0.5).

$E^{c,w}_{j \rightarrow i}$ and $E^{m,w}_{j \rightarrow i}$ denote the number of times basic block $i$ is reached from basic block $j$ with bus context $w$ and when the control flow edge $j \rightarrow i$ is correctly (incorrectly) predicted. Therefore, we have the following two constraints:

$$E^c_{j \rightarrow i} = \sum_{w \in \Omega_i} E^{c,w}_{j \rightarrow i}, \quad E^m_{j \rightarrow i} = \sum_{w \in \Omega_i} E^{m,w}_{j \rightarrow i}$$  \hspace{1cm} (20)$$

Constraints on $E^c_{j \rightarrow i}$ and $E^m_{j \rightarrow i}$ are proposed by the ILP-based formulation in Li et al. [2005]. On the other hand, $E^{c,w}_{j \rightarrow i}$ and $E^{m,w}_{j \rightarrow i}$ are bounded by the CFG structural constraints (Theiling et al. [2000]) and the constraints proposed by Equations 12-18 in Section 0.6. Note that in Equations 12-18 we only discuss the ILP constraints related to the bus contexts. Other ILP constraints, such as CFG structural constraints and user constraints, are used in our framework for an IPET implementation.

Finally, the WCET of the program maximizes the objective function in Equation 19. Any ILP solver (e.g. CPLEX) can be used for the same purpose.
0.9  Soundness and termination of analysis

In this section, we shall first provide the basic ideas for the proof of the soundness of our analysis framework and subsequently, elaborate each point.

0.9.1  Overall idea about soundness

The heart of soundness guarantee follows from the fact that we represent the timing of each pipeline stage as an interval. Recall that the active timing interval of each pipeline stage is captured by $INTV_i = [earliest[t_{i^{\text{ready}}}], latest[t_{i^{\text{finish}}}]]$. Therefore, as long as we can guarantee that $INTV_i$ is always an over-approximation of the actual timing interval of the corresponding pipeline stage in any concrete execution, we can also guarantee the soundness of our analysis. To ensure that the interval $INTV_i$ is always an over-approximation, we have to consider all possible latencies suffered by any pipeline stage. The latency of a pipeline stage, on the other hand, may be influenced by the following factors:

**Cache miss penalty**  Only NC categorized memory references may have variable latencies. Our analysis represents this variable latency as an interval $[lo, hi]$ (Equation [1]) where $lo$ ($hi$) represents the latency of a cache hit (miss).

**Functional unit latency**  Some functional units may have variable latencies depending on operands (e.g. multiplier unit). For such functional units, we consider the EX pipeline stage latency as an interval $[lo, hi]$ where $lo$ ($hi$) represents the minimum (maximum) possible latency of the corresponding functional unit.

**Contention to access functional units**  A pair of instructions may delay each other by contending for the same functional unit. Since only EX stage may suffer from contention, two different instructions may contend for the same functional unit only if the timing intervals of respective EX stages overlap. For any pipeline stage $i$, an upper bound on contention (say $CONT_{i^{\text{max}}}$) is computed by accounting the cumulative effect of contentions created by all the overlapping pipeline stages (which access the same functional unit as $i$). We do not compute a lower bound on contention and conservatively assume a safe lower bound of 0. Finally, we add $[0, CONT_{i^{\text{max}}}]$ with the timing interval of pipeline stage $i$. Clearly, $[0, CONT_{i^{\text{max}}}]$ covers all possible latencies suffered by pipeline stage $i$ due to contention.
Bus access delay  Bus access delay of a pipeline stage depends on incoming bus contexts ($O_{in}^i$). Computation of $O_{in}^i$ is always an over-approximation as evidenced by Equation 7 and Equation 9. Therefore, we can always compute the interval spanning from minimum to maximum bus delay using $O_{in}^i$ (Equation 4 and Equation 5).

In the following description, we shall argue how our analysis maintain soundness for each of these four scenarios.

0.9.2 Detailed proofs

Property 0.9.1. Functional unit latency considered during analysis is always sound. More precisely, any functional unit latency that may appear in a concrete execution, is considered during WCET analysis.

Proof. If a functional unit has fixed latency, the soundness follows trivially. However, a functional unit may have variable latency (e.g. multiplier unit). Assume $lo$ ($hi$) represents the minimum (maximum) latency that could possibly be suffered by using functional unit $f$. Our WCET analysis uses an interval $[lo, hi]$ to represent the execution latency (i.e. the latency of EX stage in the pipeline) for all the instructions which may use $f$. In this way, we are able to handle the worst case which may arise due to a lower functional unit latency.

Property 0.9.2. Cache access latencies considered during analysis is always sound. Therefore, WCET analysis considers all possible cache access latencies which may appear in a concrete execution.

Proof. Recall that memory references are classified as all-hit (AH), all-miss (AM) and unclassified (NC) in L1 and (shared) L2 cache. The soundness of categorizing a memory reference either AH or AM in L1 or (shared) L2 cache follows from the soundness of analyses proposed in Thelling et al. [2000] and Li et al. [2009]. On the other hand, the soundness of our analysis directly follows from Equation 1. Note that the latency considered for NC categorized memory reference (Equation 1) captures the entire interval — ranging from cache hit latency to cache miss latency. Therefore, our analysis can handle the worst case which may arise due to a cache hit (instead of a cache miss) for a particular memory reference.
We propose the following properties which are essential for understanding the *soundness* of shared bus analysis.

**Property 0.9.3.** Consider an execution graph of a basic block $B$ and assume $INIT_B$ represents the set of execution graph nodes without any predecessor. Assume two different execution contexts of basic block $B$ say $c_1$ and $c_2$. Further assume $O_{in}^i(c_1)$ ($O_{in}^i(c_2)$) and $O_{out}^i(c_1)$ ($O_{out}^i(c_2)$) represent the incoming and outgoing bus context, respectively, at any execution graph node $j$ with execution context $c_1$ ($c_2$). Finally assume that each EX stage in the execution context $c_2$ experiences at least as much contention as in the execution context $c_1$. For any execution graph node $j$, the following property holds: if $O_{in}^j(c_1) \not\subseteq O_{in}^j(c_2)$, then $O_{in}^i(c_1) \not\subseteq O_{in}^i(c_2)$ for at least one $i \in INIT_B$.

**Proof.** For $j \in INIT_B$, our claim trivially follows. Therefore, assume $j \notin INIT_B$. We prove our claim by contradiction. We assume that $O_{in}^i(c_1) \subseteq O_{in}^i(c_2)$ for all $i \in INIT_B$, but $O_{in}^i(c_1) \not\subseteq O_{in}^i(c_2)$. Note that any execution graph is *acyclic* and consequently, it has a valid *topological ordering*. We prove that the contradiction is invalid (i.e. $O_{in}^i(c_1) \subseteq O_{in}^i(c_2)$) by induction on the topological order $n$ of execution graph nodes.

**Base case** $n = 1$. These are the nodes in $INIT_B$. Therefore, the claim directly follows from our assumption.

**Induction step** Assume all nodes in the execution graph which have topological order $\leq k$ validates our claim. We prove that any node $j$ having topological order $\geq k + 1$ validates our claim as well. If we assume a contradiction then $O_{in}^j(c_1) \not\subseteq O_{in}^j(c_2)$. However, it is only possible if one of the following conditions hold for some predecessor $p'$ of $j$ (refer to Equation 9):

- $earliest[t_{p'}^{finish}](c_1) < earliest[t_{p'}^{finish}](c_2)$ or
- $latest[t_{p'}^{finish}](c_1) > latest[t_{p'}^{finish}](c_2)$ or
- $O_{out}^{p'}(c_1) \not\subseteq O_{out}^{p'}(c_2)$.

where $earliest[t_i^{finish}](c_1)$ ($latest[t_i^{finish}](c_1)$) and $earliest[t_i^{finish}](c_2)$ ($latest[t_i^{finish}](c_2)$) represent the *earliest* (*latest*) finish time of node $i$ in the execution contexts $c_1$ and $c_2$, re-
spectively. As any EX stage in the execution context $c_2$ experiences more contention than in
the execution context $c_1$ (our assumption), any of the above three conditions can hold only if
$O^i_{p'}(c_1) \nsubseteq O^i_{p'}(c_2)$. Following the same argument and going backward in the topological order
of the execution graph, we must have a predecessor $p_0$ which has topological order $\leq k$ and
$O^i_{p_0}(c_1) \nsubseteq O^i_{p_0}(c_2)$. This contradicts our induction hypothesis. Therefore, our initial claim was
invalid.

This property ensures that the bus contexts reaching at basic block $B$ can precisely be en-
coded by the set of bus contexts reaching at $INIT_B$, ignoring functional unit contentions (since
the bus context at any node in the execution graph can grow only if the bus context at some node
$i \in INIT_B$ grows). The following property ensures that the same is true even in the presence
of functional unit contentions.

**Property 0.9.4.** Consider an execution graph of a basic block $B$ and assume $INIT_B$ represents
the set of execution graph nodes without any predecessor. Assume two different execution
contexts of basic block $B$ say $c_1$ and $c_2$. Further assume $O^i_{j}(c_1, n)$ ($O^i_{j}(c_2, n)$) and $O^o_{j}(c_1, n)$
($O^o_{j}(c_2, n)$) represent the incoming and outgoing bus context, respectively, at any execution
graph node $j$ with execution context $c_1$ ($c_2$) and at the $n$-th iteration of pipeline modeling.
Finally assume $CR_n(c_1)$ ($CR_n(c_2)$) represents the contention relation in the execution context
$c_1$ ($c_2$) and at the $n$-th iteration of pipeline modeling. For any execution graph node $j$, the
following property holds: if $O^i_{i}(c_1, n) \subseteq O^i_{i}(c_2, n)$ for all $i \in INIT_B$ then $O^i_{j}(c_1, n) \subseteq
O^i_{j}(c_2, n)$ for any execution graph node $j$ and $CR_n(c_1) \subseteq CR_n(c_2)$ over different iterations $n$
of pipeline modeling.

**Proof.** Assume $earliest[t^rady_{i}, n](c_1)$ ($earliest[t^rady_{i}, n](c_2)$) represents the earliest ready time
of execution graph node $i$ in the execution context $c_1$ ($c_2$) and at $n$-th iteration of pipeline mod-
eling. Similarly, $latest[t^finish_{i}, n](c_1)$ ($latest[t^finish_{i}, n](c_2)$) represents the latest finish time of
execution graph node $i$ in the execution context $c_1$ ($c_2$) and at $n$-th iteration of pipeline modeling.
We prove our claim by an induction on the number of iterations ($n$) of pipeline modeling.

**Base case** $n = 1$. We start with all possible pairs of instructions in the contention relation (i.e.
we assume that every pair of instructions which may use same functional unit, can potentially
delay each other). Therefore, \( CR_1(c_1) = CR_1(c_2) \). Property 0.9.3 ensures that \( O_j^{in}(c_1, 1) \subseteq O_j^{in}(c_2, 1) \) for any execution graph node \( j \). Consequently, for any execution graph node \( j \), we can conclude that

- \( \text{earliest}[t_j^{ready}, 1](c_1) \geq \text{earliest}[t_j^{ready}, 1](c_2) \)
- \( \text{latest}[t_j^{finish}, 1](c_1) \leq \text{latest}[t_j^{finish}, 1](c_2) \)

Therefore, \( CR_2(c_1) \subseteq CR_2(c_2) \) as the timing interval of any execution graph node is coarser in the execution context \( c_2 \) compared to the corresponding timing interval in the execution context \( c_1 \).

**Induction step**  We assume that \( CR_n(c_1) \subseteq CR_n(c_2) \) and \( O_j^{in}(c_1, n) \subseteq O_j^{in}(c_2, n) \) for any execution graph node \( j \). We shall prove that \( CR_{n+1}(c_1) \subseteq CR_{n+1}(c_2) \) and \( O_j^{in}(c_1, n+1) \subseteq O_j^{in}(c_2, n+1) \) for any execution graph node \( j \). We shall prove the same by contradiction (i.e. assume that \( CR_{n+1}(c_1) \not\subseteq CR_{n+1}(c_2) \)). Informally, we have at least two execution graph nodes \( i \) and \( j \) which have disjoint timing intervals in the execution context \( c_1 \) but have overlapping timing intervals in the execution context \( c_2 \). This is only possible if one of the following conditions hold:

- \( \text{earliest}[t_i^{ready}, n+1](c_1) < \text{earliest}[t_i^{ready}, n+1](c_2) \)
- \( \text{earliest}[t_j^{ready}, n+1](c_1) < \text{earliest}[t_j^{ready}, n+1](c_2) \).
- \( \text{latest}[t_i^{finish}, n+1](c_1) > \text{latest}[t_i^{finish}, n+1](c_2) \)
- \( \text{latest}[t_j^{finish}, n+1](c_1) > \text{latest}[t_j^{finish}, n+1](c_2) \)

However, above situation may arise only if one of the following two conditions holds:

- \( O_k^{in}(c_1, n+1) \not\subseteq O_k^{in}(c_2, n+1) \) for some execution graph node \( k \). Since \( CR_n(c_1) \subseteq CR_n(c_2) \). Property 0.9.3 ensures that \( O_p^{in}(c_1, n+1) \not\subseteq O_p^{in}(c_2, n+1) \) for at least one node \( p \) which does not have any predecessor. This is a contradiction as \( O_p^{in}(c_1, n+1) = O_p^{in}(c_1, n) \) and \( O_p^{in}(c_2, n+1) = O_p^{in}(c_2, n) \) and therefore, \( O_p^{in}(c_1, n+1) = O_p^{in}(c_1, n) \subseteq O_p^{in}(c_2, n) = O_p^{in}(c_2, n+1) \).
- \( CR_n(c_1) \not\subseteq CR_n(c_2) \), which may increase \( \text{latest}[t_i^{finish}, n+1](c_1) \) with respect to the value of \( \text{latest}[t_i^{finish}, n+1](c_2) \) for some node \( i \). However, this is a contradiction of our induction hypothesis.
This property generalizes the previous Property 0.9.3 by considering functional unit contentions.

**Property 0.9.5.** Consider an execution graph of a basic block $B$ and assume $\text{INIT}_B$ represents the set of execution graph nodes without any predecessor. Assume two different execution contexts of basic block $B$ say $c_1$ and $c_2$. Further assume $O_{j}^{\text{in}}(c_1) \ (O_{j}^{\text{in}}(c_2))$ and $O_{j}^{\text{out}}(c_1) \ (O_{j}^{\text{out}}(c_2))$ represent the incoming and outgoing bus context, respectively, at any execution graph node $j$ with execution context $c_1 \ (c_2)$. If $O_{i}^{\text{in}}(c_1) \subseteq O_{i}^{\text{in}}(c_2)$ for all $i \in \text{INIT}_B$, WCET of basic block $B$ in the execution context $c_2$ is always at least equal to the WCET of basic block $B$ in the execution context $c_1$.

**Proof.** This claim follows directly from Properties 0.9.3-0.9.4. If $O_{i}^{\text{in}}(c_1) \subseteq O_{i}^{\text{in}}(c_2)$ for all nodes $i \in \text{INIT}_B$, then according to Properties 0.9.3-0.9.4 $O_{j}^{\text{in}}(c_1) \subseteq O_{j}^{\text{in}}(c_2)$ for any execution graph node $j$. Since the bus context at any execution graph node with the execution context $c_2$ subsumes the respective bus contexts with the execution context $c_1$, we can conclude that the WCET of basic block $B$ with the execution context $c_2$ is at least equal to the WCET of basic block $B$ with the execution context $c_1$.

**Property 0.9.6.** Consider any non-nested loop $l$. Assume $O_{i}^{\text{in}}(m)$ represents the incoming bus context of any execution graph node $i$ at $m$-th iteration of loop. Consider two different iterations $m'$ and $m''$ of loop $l$. If $O_{x_i}^{\text{in}}(m') \subseteq O_{x_i}^{\text{in}}(m'')$ for all $x_i \in \pi_i^{\text{in}}$, $O_{x_i}^{\text{in}}(m'+1) \subseteq O_{x_i}^{\text{in}}(m''+1)$ for all $x_i \in \pi_i^{\text{in}}$. Moreover, WCET of any basic block inside loop $l$ at iteration $m''$ must be at least equal to the WCET of the corresponding basic block at iteration $m'$.

**Proof.** By definition, $\pi_i^{\text{in}}$ corresponds to the set of pipeline stages which resolve *loop carried dependency* (either due to resource constraints, pipeline structural constraints or true data dependency). This direct dependency is specified through directed edges in the execution graph (as shown in Figure 3). We first prove that $O_{j}^{\text{in}}(m') \subseteq O_{j}^{\text{in}}(m'')$ for any execution graph node $j$ that corresponds to some instruction inside $l$. We prove our claim by induction on the topological order $n$ of basic blocks in $l$. 

27
**Base case** \( n = 1 \). This is the loop header \( H \). By using an exactly similar proof as in properties 0.9.3–0.9.4 we can show that if \( O_{i1}^{in}(m') \subseteq O_{i1}^{in}(m'') \) for all \( x i \in \pi_{i1}^{in} \), \( O_{i1}^{in}(m') \subseteq O_{i1}^{in}(m'') \) for any node \( i \) in the execution graph of \( H \).

**Induction step** Assume our claim holds for all basic blocks having topological order \( \leq k \). We shall prove that our claim holds for all basic blocks having topological order \( \geq k + 1 \). However, using our methodology for proving Properties 0.9.3–0.9.4 we can easily show that if the bus context for some basic block (having topological order \( \geq k + 1 \)) at iteration \( m'' \) is not an over-approximation of the bus context of the same basic block at iteration \( m' \), it could be either of two following reasons:

- The bus context at iteration \( m'' \) is not an over-approximation of the bus context at iteration \( m' \) for some basic block having topological order \( \leq k \), contradicting our induction hypothesis;
- For some \( x i \in \pi_{i1}^{in} \), \( O_{i1}^{in}(m') \not\subseteq O_{i1}^{in}(m'') \), contradicting our assumption.

Since the bus contexts computed at each basic block at iteration \( m'' \) subsume the corresponding bus contexts at iteration \( m' \), \( O_{i1}^{in}(m' + 1) \subseteq O_{i1}^{in}(m'' + 1) \) for all \( x i \in \pi_{i1}^{in} \). For the same reason, WCET of any basic block inside \( l \) at \( m'' \)-th iteration is at least equal to the WCET of the corresponding basic block at iteration \( m' \).

Recall that to track the bus contexts at different loop iterations, we construct a flow graph \( G_i^s \). We terminate the construction of \( G_i^s \) after \( k (k \geq 1) \) iterations only if for all \( i \in \pi_{i1}^{in} \), \( O_i^{in}(k) \subseteq O_i^{in}(j) \) where \( 1 \leq j < k \). We add a backedge from \( k - 1 \)-th bus context to \( j \)-th bus context to terminate the construction of \( G_i^s \). The bus context at some loop iteration \( n \) is computed from \( G_i^s \) by following a path of length \( n \) from the initial node. In case \( n \) is less than the number of nodes in \( G_i^s \), it is straightforward to see that the computed bus context is always an over-approximation (as evidenced by Equation 7 and Equation 9). In case \( n \) is more than the number of nodes in \( G_i^s \) (i.e. backedge in \( G_i^s \) is followed at least once to compute the bus context), the above property ensures that the bus context computed by the flow graph is always an over-approximation.

In the following property, we shall generalize the result for any loop (nested or non-nested).
**Property 0.9.7.** Consider any loop $l$. Assume $O_i^{in}(m)$ represents the incoming bus context of any execution graph node $i$ at $m$-th iteration of loop. Consider two different iterations $m'$ and $m''$ of loop $l$. If $O_i^{in}(m') \subseteq O_i^{in}(m'')$ for all $x_i \in \pi_i^{in}$, $O_i^{in}(m'+1) \subseteq O_i^{in}(m''+1)$ for all $x_i \in \pi_i^{in}$. Moreover, if $l$ contains some loop $l'$, $O_j^{exit}$ computed at $m''$-th iteration of $l$ always over-approximates $O_j^{exit}$ computed at $m'$-th iteration of $l$, for every $x_j \in \pi_{l'}^{out}$.

**Proof.** Let us first consider some loop $l$ which contains only non-nested loops. Let us assume a topological order of all inner loops inside $l$ and assume $l^x$ represents the inner loop contained in $l$, which is preceded by $x-1$ other inner loops inside $l$, in topological order. We first prove that $O_j^{in}(m') \subseteq O_j^{in}(m'')$ for any execution graph node $j$ that corresponds to some instruction inside $l$. We also prove that for any inner loop $l^x$ and for all $j \in \pi_{l^x}^{out}$, $O_j^{exit}$ computed at $m''$-th iteration of $l$ is always an over-approximation of $O_j^{exit}$ computed at $m'$-th iteration of $l$.

For any basic block $i$ inside $l$, assume that $n_i$ is the number of loop exit edges appearing prior in topological order of $i$. We assume that each loop has a single exit node. If some loop has multiple exits, we can assume an empty node which post-dominates all the exit nodes of the loop. We prove our claim by induction on $n_i$.

**Base case** $n_i = 0$. Therefore, we have the two following possibilities:

- (Case I) $i$ is a basic block which is immediately enclosed by loop $l$.
- (Case II) $i$ is a basic block which is immediately enclosed by loop $l^1$ and $l^1$ is the *first loop* contained inside $l$, following a topological order.

For Case I, Property 0.9.6 ensures that $O_j^{in}(m') \subseteq O_j^{in}(m'')$ for all nodes $j$ that corresponds to the instructions in basic block $i$.

For Case II, basic block $i$ may have different bus contexts at different iterations of loop $l^1$. We shall prove that the bus context computed for basic block $i$ at any iteration of $l^1$ validates our claim. Assume $O_j^{in}(x,x')$ ($O_j^{out}(x,x')$) represents the incoming (outgoing) bus context at the execution graph node $j$ at $x$-th iteration of $l$ and at $x'$-th iteration of $l^1$. Properties 0.9.3 ensure that $O_j^{in}(x,1) \subseteq O_j^{in}(m,n,1)$ for all $x_j \in \pi_i^{in}$. Therefore, applying Property 0.9.6 on loop $l^1$, for any execution graph node $j$ and for any iteration $n$ of loop $l^1$, we get $O_j^{in}(m',n) \subseteq O_j^{in}(m'',n)$. Therefore, $O_i^{exit}$ for any $i \in \pi_{l^1}^{out}$ (recall that $O_i^{exit}$ represents
the bus context exiting the loop $l^1$ from node $i$ computed at $m''$-th iteration of loop $l$ is an over-approximation of $O^\text{exit}_i$ computed at $m'$-th iteration of loop $l$.

**Induction step** Assume our claim holds for all basic blocks $i$ having $n_i \leq k$. Therefore, $O^\text{in}_j(m') \subseteq O^\text{in}_j(m'')$ for any execution graph node $j$ that corresponds to the instructions of any basic block $i$ (having $n_i \leq k$). Moreover, for any inner loop $l^k$ and for all $j \in \pi^{\text{out}}_{l^k}$, $O^\text{exit}_j$ computed at $m''$-th iteration of $l$ is always an over-approximation of $O^\text{exit}_j$ computed at $m'$-th iteration of $l$.

We shall prove that our claim holds for all basic blocks having $n_i = k + 1$. As described in the preceding, we have the two following cases:

- (Case I) $i$ is a basic block which is immediately enclosed by loop $l$.
- (Case II) $i$ is a basic block which is immediately enclosed by some loop $l^{k+1}$, where $l^{k+1}$ is the loop contained inside $l$ and $k$ different loops inside $l$ precedes $l^{k+1}$ in topological order.

For Case I, using our methodology for proving Properties 0.9.3-0.9.4, we can easily show that if the bus context for some basic block $i$ (having $n_i = k + 1$) at iteration $m''$ is not an over-approximation of the bus context of the same basic block at iteration $m'$, it could be due to any of the three following reasons:

- The bus context at iteration $m''$ is not an over-approximation of the bus context at iteration $m'$ for some basic block $j$ having $n_j \leq k$, contradicting our induction hypothesis;
- There exists some loop $l^x$ which appears prior to $i$ in topological order but $O^\text{exit}_i$ computed at $m''$-th iteration of loop $l$ is not an over-approximation of $O^\text{exit}_i$ computed at $m'$-th iteration of loop $l$ for some $i \in \pi^{\text{out}}_{l^x}$. Since $l^x$ appears prior in topological order of $i$, $x \leq k$. This also violates our induction hypothesis.
- For some $x_i \in \pi^{\text{in}}_i, O^\text{in}_i(m') \nsubseteq O^\text{in}_i(m'')$, contradicting our assumption.

Now consider Case II. Assume $O^\text{in}_j(x, x')$ ($O^\text{out}_j(x, x')$) represents the incoming (outgoing) bus context at the execution graph node $j$ at $x$-th iteration of $l$ and at $x'$-th iteration of $l^{k+1}$. According to our induction hypothesis and the argument provided above, we get $O^\text{in}_j(m', 1) \subseteq O^\text{in}_j(m'', 1)$ for all $j \in \pi^{\text{in}}_{l^{k+1}}$. Therefore, applying Property 0.9.6 on loop $l^{k+1}$, for any execution
graph node \( j \) and for any iteration \( n \) of loop \( l^{k+1} \), we get \( O_{j}^{in}(m', n) \subseteq O_{j}^{in}(m'', n) \). Consequently, for any \( i \in \pi_{l^{k+1}}^{out} \), \( O_{i}^{exit} \) computed at \( m'' \)-th iteration of loop \( l \) is an over-approximation of \( O_{i}^{exit} \) computed at \( m' \)-th iteration of loop \( l \). This completes our induction.

Finally, we conclude that \( O_{j}^{in}(m') \subseteq O_{j}^{in}(m'') \) for any execution graph node \( j \) that corresponds to some instruction in \( l \). Consequently, \( O_{x_{i}}^{in}(m' + 1) \subseteq O_{x_{i}}^{in}(m'' + 1) \) for all \( x_{i} \in \pi_{l}^{in} \).

From the above argument, it is now straightforward to see that the property also holds for any nested loop by proving the claims in a bottom up fashion of loop nests (i.e. an induction on the level of loop nests starting from the innermost loop).

**Property 0.9.8.** (Termination Property) Consider two instructions \( p \) and \( q \) of basic block \( B \). \((p, q) \in CR\) if and only if \( p \) and \( q \) may contend for the same functional unit. \( CR \) is called the contention relation. Assume \( CR_{n} \) represents the contention relation at \( n \)-th iteration of pipeline modeling. Set of elements in \( CR_{n} \) monotonically decreases across different iterations \( n \) of pipeline modeling.

**Proof.** We prove the above claim by induction on number of iterations taken by the pipeline modeling. For some execution graph node \( i \), assume \( O_{i}^{in}(n) \) \((O_{i}^{out}(n))\) represents the incoming (outgoing) bus context at iteration \( n \). Also assume \( earliest[t_{i}^{ready}, n] \) \((latest[t_{i}^{finish}, n])\) represents the earliest (latest) ready (finish) time of execution graph node \( i \) at iteration \( n \).

**Base case** \( n = 1 \). We start with all possible pairs of instructions in the contention relation (i.e. we assume that every pair of instructions which may use same functional unit can potentially delay each other). Therefore, the set of elements in the contention relation trivially decreases after the first iteration (i.e. \( CR_{2} \subseteq CR_{1} \)).

**Induction step** We assume that \( CR_{n} \subseteq CR_{n-1} \) and we shall prove that \( CR_{n+1} \subseteq CR_{n} \). We prove the same by contradiction (i.e. assume that \( CR_{n+1} \nsubseteq CR_{n} \)). Informally, we have at least two execution graph nodes \( i \) and \( j \) which have disjoint timing intervals at iteration \( n \) but overlapping timing intervals at iteration \( n + 1 \). This is only possible if one of the following conditions hold:

- \( earliest[t_{i}^{ready}, n+1] < earliest[t_{i}^{ready}, n] \) (or \( earliest[t_{j}^{ready}, n+1] < earliest[t_{j}^{ready}, n] \)).
• latest[$t_i^{finish}, n + 1]$ > latest[$t_i^{finish}, n$] (or latest[$t_j^{finish}, n + 1$] > latest[$t_j^{finish}, n$]).

However, above situation may arise only if one of the following two conditions hold: 1) $O_k^{in}(n + 1) \not\subseteq O_k^{in}(n)$ for some execution graph node $k$. Since $CR_n \subseteq CR_{n-1}$, Property 0.9.4 ensures $O_p^{in}(n + 1) \not\subseteq O_p^{in}(n)$ for at least one node $p$ which does not have any predecessor. This is a contradiction as $O_p^{in}(n + 1) = O_p^{in}(n)$. 2) $CR_n \not\subseteq CR_{n-1}$, which leads to more contention at $n$-th iteration and thereby increasing latest[$t_i^{finish}, n + 1$] for some node $i$. However, this is a contradiction of our induction hypothesis.

This property ensures that our iterative framework always terminates in the presence of shared cache and shared bus. □

**Property 0.9.9.** Computation of $O_i^{in}$ and $O_i^{out}$ is always sound.

**Proof.** This follows directly from the previous properties. Property 0.9.6 ensures that we include all possible contexts for a basic block inside loop. Equation 10 and Equation 11 ensure that we include all possible TDMA offsets from different program paths. As contention decreases monotonically over different iterations of pipeline modeling (Property 0.9.8), Equation 9 and Equation 7 ensure that the value of $O_i^{in}$ and $O_i^{out}$ are sound over-approximations of respective bus contexts. Finally, the soundness of the analysis presented in Kelter et al. [2011] guarantees that we always compute an overapproximation of bus contexts at loop exit.

Essentially, we show that the search space of possible bus contexts is never pruned throughout the program. Therefore, our analysis maintain soundness when a lower bus delay may lead to global worst case scenario. □

Finally, we conclude that the longest acyclic path search in the execution graph always results in a sound estimation of basic block WCET. Moreover, we are able to consider an overapproximation of all possible bus contexts if a basic block executes with multiple bus contexts (Properties 0.9.6, 0.9.7). The IPET approach, on the other hand, searches for the longest feasible program path to ensure a sound estimation of whole program’s WCET.
0.10 Experimental evaluation

Experimental setup

We have chosen moderate to large size benchmarks from [Gustafsson et al. 2010], which are generally used for timing analysis. The code size of the benchmarks ranges from 2779 bytes (bsort100) to 118351 bytes (nsichneu), with an average code size of 18500 bytes. Individual benchmarks are compiled into simplescalar PISA (Portable Instruction Set Architecture) [Austin et al. 2002] — a MIPS like instruction set architecture. We use the simplescalar gcc cross compiler with optimization level `-O2` to generate the PISA compliant binary of each benchmark. The control flow graph (CFG) of each benchmark is extracted from its PISA compliant binary and is used as an input to our analysis framework.

To validate our analysis framework, the simplescalar toolset [Austin et al. 2002] was extended to support the simulation of shared cache and shared bus. The simulation infrastructure is used to compare the estimated WCET with the observed WCET. Observed WCET is measured by simulating the program for a few program inputs. Nevertheless, we would like to point out that the presence of a shared cache and a shared bus makes the realization of the worst case scenario extremely challenging. In the presence of a shared cache and a shared bus, the worst case scenario depends on the interleavings of threads, which are running on different cores. Consequently, the observed WCET result in our experiments may sometimes highly under-approximate the actual WCET.

For all of our experiments, we present the WCET overestimation ratio, which is measured as $\frac{\text{Estimated WCET}}{\text{Observed WCET}}$. For each reported overestimation ratio, the system configuration during the analysis (which computes Estimated WCET) and the measurement (which computes Observed WCET) are kept identical. Unless otherwise stated, our analysis uses the default system configuration in Table 1 (as shown by the column “Default settings”). Since the data cache modeling is not yet included in our current implementation, all data accesses are assumed to be L1 cache hits (for analysis and measurement both).

To check the dependency of WCET overestimation on the type of conflicting task (being run in parallel on a different core), we use two different tasks to generate the inter-core conflicts — 1) jfdctint, which is a single path program and 2) statemate, which has a huge number of paths. In our experiments (Figures 5-7), we use jfdctint to generate inter-core

Due to the absence of any infeasible program path, inter-core conflicts generated by a single path program (e.g. jfdctint) can be more accurately modeled compared to a multi-path program (e.g. statemate). Therefore, in the presence of a shared cache, we expect a better WCET overestimation ratio for the first half of the benchmarks (i.e. matmult to nsichneu) compared to the second half (i.e. edn to st).

To measure the WCET overestimation due to cache sharing, we compare the WCET result with two different design choices, where the level 2 cache is partitioned. For a two-core system, two different partitioning choices are explored: first, each partition has the same number of cache sets but has half the number of ways compared to the original shared cache (called vertical partitioning). Secondly, each partition has half the number of cache sets but has the same number of ways compared to the original shared cache (called horizontal partitioning). In our default configuration, therefore, each core is assigned a 2-way associative, 2 KB L2 cache in the vertical partitioning, whereas each core is assigned a 4-way associative, 2 KB L2 cache in the horizontal partitioning.

Finally, to pinpoint the source of WCET overestimation, we can selectively turn off the analysis of different micro-architectural components. We say that a micro-architectural component has perfect setting if the analysis of the same is turned off (refer to column “Perfect settings” in Table 1).
Basic analysis result

Effect of caches Figure 5 shows the WCET overestimation ratio with respect to different L1 and L2 cache settings in the presence of a perfect branch predictor and a perfect shared bus. Results show that we can reasonably bound the WCET overestimation ratio except for nsichneu. The main source of WCET overestimation in nsichneu comes from the path analysis and not due to the micro-architectural modeling. This is expected, as nsichneu contains more than two hundred branch instructions and many infeasible paths. These infeasible paths can be eliminated by providing additional user constraints into our framework and hence improving the result. We also observe that the partitioned L2 caches may lead to a better WCET overestimation compared to the shared L2 caches, with the vertical L2 cache partitioning almost always working as the best choice. The positive effect of the vertical cache partitioning is visible in adpcm, where the overestimation in the presence of a shared cache rises. This is due to the difficulty in modeling the inter-core cache conflicts from statemate (a many-path program being run in parallel).

Effect of speculative execution As we explained in Section 0.7 the presence of a branch predictor and speculative execution may introduce additional computation cycles for executing a mispredicted path. Moreover, speculative execution may introduce additional cache conflicts from a mispredicted path. The results in Figure 6(a) and Figure 6(b) show the effect of speculation in L1 and L2 cache, respectively. Mostly, we do not observe any sudden spikes in the WCET overestimation just due to speculation. adpcm shows some reasonable increase in WCET overestimation with L2 caches and in the presence of speculation (Figure 6(b)). This increase in
Figure 6: (a) Effect of speculation on L1 cache, (b) effect of speculation on partitioned and shared L2 caches

the overestimation ratio can be explained from the overestimation arising in the modeling of the effect of speculation in cache (refer to Section 0.7). Due to the abstract join operation to combine the cache states in correct and mispredicted path, we may introduce some spurious cache conflicts. Nevertheless, our approach for modeling the speculation effect in cache is scalable and produces tight WCET estimates for most of the benchmarks.

Effect of shared bus  Figure 7 shows the WCET overestimation in the presence of a shared cache and a shared bus. We observe that our shared bus analysis can reasonably control the overestimation due to the shared bus. Except for edn and nsichneu, the overestimation in the presence of a shared cache and a shared bus is mostly equal to the overestimation when shared bus analysis is turned off (i.e. a perfect shared bus). Recall that each overestimation ratio is computed by performing the analysis and the measurement on identical system configuration. Therefore, the analysis and the measurement both includes the shared bus delay only when the
shared bus is enabled. For a perfect shared bus setting, both the analysis and the measurement consider a zero latency for all the bus accesses. As a result, we also observe that our shared bus analysis might be more accurate than the analysis of other micro-architectural components (e.g., in case of nsichneu, expint and fir, where the WCET overestimation ratio in the presence of a shared bus might be less than the same with a perfect shared bus). In particular, nsichneu shows a drastic fall in the WCET overestimation ratio when the shared bus analysis is enabled. For nsichneu, we found that the execution time is dominated by shared bus delay, which is most accurately computed by our analysis for this benchmark. On the other hand, we observed in Figure 5 that the main source of WCET overestimation in nsichneu is path analysis, due to the presence of many infeasible paths. Consequently, when shared bus analysis is turned off, the overestimation arising from path analysis dominates and we obtain a high WCET overestimation ratio. Average WCET overestimation in the presence of both a shared cache and a shared bus is around 50%.

**WCET analysis sensitivity w.r.t. micro-architectural parameters**

In this section, we evaluate the WCET overestimation sensitivity with respect to different micro-architectural parameters. For the following experiments, the reported WCET overestimation denotes the geometric mean of the term $\frac{\text{Estimated WCET}}{\text{Observed WCET}}$ over all the different benchmarks.

**WCET sensitivity w.r.t. L1 cache size**  Figure 8(a) and Figure 8(b) show the geometric mean of WCET overestimation for different L1 cache sizes, with and without speculation, respectively. To keep the L2 cache bigger than the L1 cache, total L2 cache is kept at 4-way, 16 KB for all the experiments in Figures 8(a)-(b). Therefore, for horizontally and vertically partitioned L2
Figure 8: WCET overestimation sensitivity w.r.t. L1 cache (a) without speculation, (b) with speculation

cache architectures, each core uses an 8 KB L2 cache. Naturally, in the presence of speculation, the overestimation is slightly higher. However, our framework is able to maintain an average overestimation ratio around 20% without speculation and around 40% with speculation.

WCET sensitivity w.r.t. L2 cache size  Figure 9(a) and Figure 9(b) show the geometric mean of WCET overestimation for different L2 cache sizes, with and without speculation, respectively. On average, WCET overestimation in the presence of shared L2 cache is higher compared to partitioned L2 cache architectures. As pointed out earlier, this is due to the inherent difficulties in modeling the inter-core cache conflicts. Nevertheless, our analysis framework captures an average overestimation around 40% (50%) without (with) speculation over different L2 cache settings.

WCET sensitivity w.r.t. different pipelines We have done experiments for different pipelines. Figure 10(a) (without speculation) and Figure 10(b) (with speculation) show the WCET over-

(b)

Figure 9: WCET overestimation sensitivity w.r.t. L2 cache (a) without speculation, (b) with speculation.

WCET sensitivity w.r.t. bus slot length

Finally, we show how the WCET overestimation is affected with respect to bus slot length. Figure 11 shows the WCET overestimation sensitivity with respect to different bus slot lengths. With very high bus slot lengths (e.g. 70 or 80 cycles), WCET overestimation normally increases (as shown in Figure 11). This is due to the fact that with higher bus slot lengths, the search space for possible bus contexts (or set of TDMA offsets) increases. As a result, it is less probable to expose the worst case scenario in simulation with...
higher bus slot lengths.

**Analysis time**

We have performed all the experiments on an 8 core, 2.83 GHz Intel Xeon machine having 4 GB of RAM and running Fedora Core 4 operating system. Table 2 reports the maximum analysis time when the shared bus analysis is disabled and Table 3 reports the maximum analysis time when all the analyses are enabled (i.e. cache, shared bus and pipeline). Recall from Section 0.4 that our WCET analysis framework is broadly composed of two different parts, namely, micro-architectural modeling and implicit path enumeration (IPET) through integer linear programming (ILP). The column labeled “µ arch” captures the time required for micro-architectural modeling. On the other hand, the column labeled “ILP” captures the time required for path analysis through IPET.

In the presence of speculative execution, number of mispredicted branches is modeled by integer linear programming [Li et al. 2005]. Such an ILP-based branch predictor modeling,
Figure 11: WCET overestimation sensitivity w.r.t. different bus slot length (with and without speculative execution)

therefore, increases the number of constraints which need to be considered by the ILP solver. As a result, the ILP solving time increases in the presence of speculative execution (as evidenced by the second rows of both Table 2 and Table 3).

Shared bus analysis increases the micro-architectural modeling time (as evidenced by Table 3) and the analysis time usually increases with the bus slot length. The time for the shared bus analysis generally appears from tracking the bus context at different pipeline stages. A higher bus slot length usually leads to a higher number of bus contexts to analyze, thereby increasing the analysis time.

In Table 2 and Table 3 we have only presented the analysis time for the longest running benchmark (nsichneu) from our test-suite. For any other program used in our experiments, the entire analysis (micro-architectural modeling and ILP solving time) takes around 20-30 seconds on average to finish.

The results reported in Table 2 show that the ILP-based modeling of branch predictor usually increases the analysis time. Therefore, for a more efficient but less precise analysis of branch predictors, one can explore different techniques to model branch predictors, such as abstract interpretation. Shared bus analysis time can be reduced by using different offset abstractions, such as interval instead of an offset set. Nevertheless, the appropriate choice of analysis method and abstraction depends on the precision-scalability tradeoff required by the user.

0.11 Extension of shared cache analysis

Our discussion on cache analysis has so far concentrated on the least-recently-used (LRU) cache replacement policies. However, a widely used cache replacement policy is first-in-first-out (FIFO). FIFO cache replacement policy has been used in embedded processors such as ARM9 and ARM11 [Reineke et al. 2007]. Recently, abstract interpretation based analysis of FIFO replacement policy has been proposed in [Grund and Reineke 2009, 2010a] for single level caches and for multi-level caches in [Hardy and Puaut 2011]. In this section, we shall discuss the extension of our shared cache analysis for FIFO cache replacement policy. We shall also show that such an extension will not change the modeling of timing interactions among shared cache and other basic micro-architectural components (e.g. pipeline and branch predictor).

0.11.1 Review of cache analysis for FIFO replacement

We use the must cache analysis for FIFO replacement as proposed in [Grund and Reineke 2009]. In FIFO replacement, when a cache set is full and still the processor requests fresh memory blocks (which map to the same cache set), the first cache line entering the respective cache set (i.e. first-in) is replaced. Therefore, the set of tags in a k-way FIFO abstract cache set (say $A_k$)
can be arranged from last-in to first-out order (Grund and Reineke [2009]) as follows:

\[ A_s = [T_1, T_2, \ldots, T_k] \]  

where each \( T_i \subseteq T \) and \( T \) is the set of all cache tags. Unlike LRU, cache state never changes upon a \textit{cache hit} with FIFO replacement policy. Therefore, the cache state update on a memory reference depends on the \textit{hit-miss} categorization of the same memory reference. Assume that a memory reference belongs to cache tag \textit{tag} \( i \). The FIFO abstract cache set \( A_s = [T_1, T_2, \ldots, T_k] \) is updated on the access of \( \textit{tag} \) \( i \) as follows:

\[
\tau([T_1, T_2, \ldots, T_k], \textit{tag} \) \( i \) \) =
\begin{align*}
&[T_1, T_2, \ldots, T_k], \text{ if } \textit{tag} \) \( i \in \bigcup_i T_i; \\
&\{\textit{tag} \) \( i \}, T_2, \ldots, T_{k-1}\}, \text{ if } \textit{tag} \) \( i \notin \bigcup_i T_i \wedge |\bigcup_i T_i| = k; \\
&[\phi, T_2, \ldots, T_{k-1} \cup \{\textit{tag} \) \( i \}], \text{ otherwise.}
\end{align*}
\]  

The first scenario captures a \textit{cache hit} and the second scenario captures a \textit{cache miss}. Third scenario appears when the static analysis cannot accurately determine the \textit{hit-miss} categorization of the memory reference.

The \textit{abstract join} function for the FIFO must cache analysis is exactly same as the LRU must cache analysis. The join function between two abstract FIFO cache sets computes the intersection of the abstract cache sets. If a cache tag is available in both the abstract cache sets, the \textit{right most} relative position of the cache tag is captured after the join operation.

### 0.11.2 Analysis of shared cache with FIFO replacement

We implement the \textit{must cache analysis} for FIFO replacement as described in the preceding. To distinguish the cold cache misses at the first iterations of loops and different procedure calling contexts, our cache analysis employs the \textit{virtual-inline-virtual-unrolling} (VIVU) approach (as described in [Theiling et al. 2000]). After analyzing the L1 cache memory references are categorized as \textit{all-hit} (AH), \textit{all-miss} (AM) or \textit{unclassified} (NC). AM and NC categorized memory references may access the L2 cache and therefore, the L2 cache state is updated for the memory references which are categorized AM or NC in the L1 cache (as in [Hardy and Puaut 2011]).

To analyze the shared cache, we used our previous work on shared cache [Li et al. 2009] for LRU cache replacement policy. [Li et al. 2009] employs a separate shared cache conflict analysis.
phase. For FIFO replacement policy too, we can use the exactly same idea to analyze the set of inter-core cache conflicts. Shared cache conflict analysis may change the categorization of a memory reference from all-hit (AH) to unclassified (NC). For the sake of illustration, assume a memory reference which accesses the memory block $m$. This analysis phase first computes the number of unique conflicting shared cache accesses from different cores. Then it is checked whether the number of conflicts from different cores can potentially replace $m$ from shared cache. More precisely, for an $N$-way set associative cache, hit/miss categorization (CHMC) of corresponding memory reference is changed from all-hit (AH) to unclassified (NC) if and only if the following condition holds:

$$N - AGE_{fifo}(m) < |M_c(m)|$$  \hspace{1cm} (23)

where $|M_c(m)|$ represents the number of conflicting memory blocks from different cores which may potentially access the same L2 cache set as $m$. $AGE_{fifo}(m)$ represents the relative position of memory block $m$ in the FIFO abstract cache set and in the absence of inter-core cache conflicts. Recall that the memory blocks (or the tags) are arranged according to the last-in to first-out order in the FIFO abstract cache set. Therefore, the term $N - AGE_{fifo}(m)$ captures the maximum number of fresh memory blocks which can enter the FIFO cache before $m$ being evicted out.

### 0.11.3 Interaction of FIFO cache with pipeline and branch predictor

As described in the preceding, after the FIFO shared cache analysis, memory references are categorized as all-hit (AH), all-miss (AM) or unclassified (NC). In the presence of pipeline, such a categorization of instruction memory references add computation cycle with the instruction fetch (IF) stage. Therefore, we use Equation 1 to compute the latency suffered by cache hit/miss and propagate the latency through different pipeline stages.

Recall from Section 0.7.1 that speculative execution may introduce additional cache conflicts. In Section 0.7.1 we proposed to modify the abstract interpretation based cache analysis to handle the effect of speculative execution on cache. From Figure 4 we observe that our solution is independent of the cache replacement policies concerned. Our proposed modification performs an abstract join operation on the cache states along the correct and mispredicted path (as shown in Figure 4). Therefore, for FIFO replacement polices the abstract join operation
is performed according to the FIFO replacement analysis (instead of LRU join operation we performed in case of LRU caches).

### 0.11.4 Experimental result

![Bar chart](image)

**Figure 12**: Analysis of cache in the presence of FIFO replacement policy (a) WCET overestimation w.r.t. different L2 cache architectures, (b) WCET overestimation in the presence of FIFO cache and speculative execution

Figure 12 demonstrates our WCET analysis experience with FIFO replacement policy. We have used the exactly same experimental setup as mentioned in Section 0.10. Figure 12(a) shows the WCET overestimation ratio in the absence of speculative execution and Figure 12(a) shows the same in the presence of branch predictor. In general, our analysis framework can reasonably bound the WCET overestimation for FIFO cache replacement, except for fdct. Such an overestimation for fdct is solely due to the presence of a FIFO cache and not due to the presence of cache sharing, as clearly evidenced by Figure 12(a). However, as mentioned in Berg [2006], the observed worst-case for FIFO replacement may highly under-approximate the true worst case due to the domino effect. Otherwise, our results in Figure 12(a) show that FIFO
is a reasonably good alternative of LRU replacement even in the context of shared caches.

Figure 12(b) shows that our modeling of the interaction between FIFO cache and the branch predictor does not much affect the WCET overestimation. As evidenced by Figure 12(b), the increase in the WCET overestimation is minimal due to the speculation.

### 0.11.5 Other cache organizations

In the preceding, we have discussed the extension of our WCET analysis framework with FIFO replacement policy. We have shown that as long as the cache tags in an abstract cache set can be arranged according to the order of their replacement, our shared cache conflict analysis can be integrated. As a result, our modeling for the timing interaction among (shared) cache, pipeline and branch predictor is independent of the underlying cache replacement policy. Nevertheless, for some cache replacement policies, arranging the cache tags according to the order of their replacement poses a challenge (e.g. PLRU [Grund and Reineke 2010b]). Cache analysis based on relative competitiveness [Reineke et al. 2007] tries to analyze a cache replacement policy with respect to an equivalent LRU cache, but with different parameters (e.g. associativity). Any cache replacement analysis based on relative competitiveness can directly be integrated with our WCET analysis framework. Nevertheless, more precise analysis than the ones based on relative competitiveness can be designed, as shown in [Grund and Reineke 2010b] for PLRU policy. However, we believe that designing more precise cache analysis is outside the scope of this paper. The purpose of our work is to propose a unified WCET analysis framework and any precision gain in the existing cache analysis technique will directly benefit our framework by improving the precision of WCET prediction.

In this paper, we have focused on the non-inclusive cache hierarchy. In multi-core architectures, inclusive cache hierarchy may limit performance when the size of the largest cache is not significantly larger than the sum of the smaller caches. Therefore, processor architects sometimes resort to non-inclusive cache hierarchies [Zahran et al. 2007]. On the other hand, inclusive cache hierarchies greatly simplify the cache coherence protocol. The analysis of inclusive cache hierarchy requires to take account of the invalidations of certain cache lines to maintain the inclusion property (as shown in [Hardy and Puaut 2011] for multi-level private cache hierarchies). The analysis in [Hardy and Puaut 2011] first analyzes the multi-level caches for general non-inclusive cache hierarchies and a post-processing phase may change the categorization of a memory reference from all-hit (AH) to unclassified (NC). Our shared cache conflict
analysis phase can be applied on this reduced set of AH categorized memory reference for inclusive caches, keeping the rest of our WCET analysis framework entirely unchanged. Therefore, we believe that the inclusive cache hierarchies do not pose any additional challenge in the context of shared caches and the analysis of such cache hierarchies can easily be integrated, keeping the rest of our WCET analysis framework unchanged.

0.12 Conclusion

In this paper, we have proposed a sound WCET analysis framework by modeling different micro-architectural components and their interactions in a multi-core processor. Our analysis framework is also sound in the presence of timing anomalies. Our experiments suggest that we can obtain tight WCET estimates for the majority of benchmarks in a variety of micro-architectural configurations. Apart from design space exploration, we believe that our framework can be used to figure out the major sources of overestimation in multi-core WCET analysis. As a result, our framework can help in designing predictable hardware for real-time applications and it can also help writing real-time applications for the predictable execution in multi-cores.
