Bioinformatics and Biomarker Discovery Part 2: Tools

Limsoon Wong 28 August 2008

Outline

- Overview of Supervised Learning
- Decision Trees Ensembles
 - Bagging
- Other Methods
 - K-Nearest Neighbour
 - Bayesian Approach

Overview of Supervised Learning

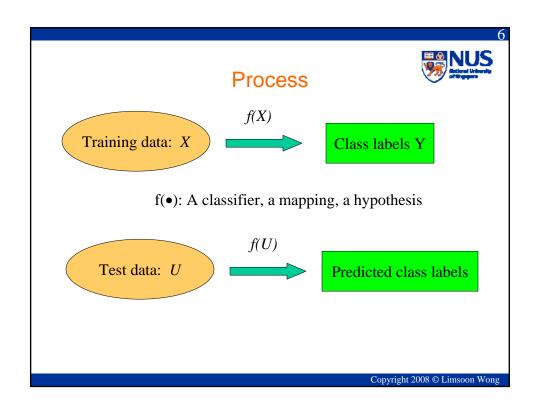

Computational Supervised Learning

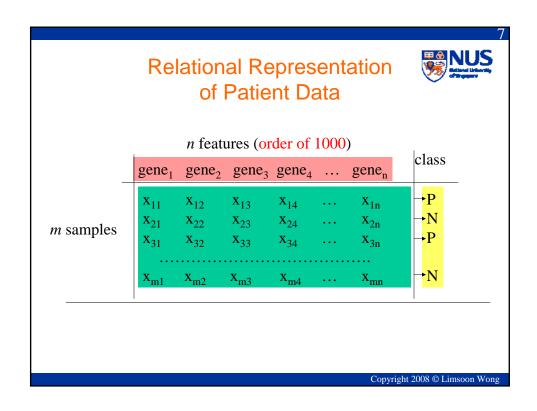

- Also called classification
- Learn from past experience, and use the learned knowledge to classify new data
- Knowledge learned by intelligent algorithms
- Examples:
 - Clinical diagnosis for patients
 - Cell type classification

Data

- Classification application involves > 1 class of data. E.g.,
 - Normal vs disease cells for a diagnosis problem
- Training data is a set of instances (samples, points) with known class labels
- Test data is a set of instances whose class labels are to be predicted

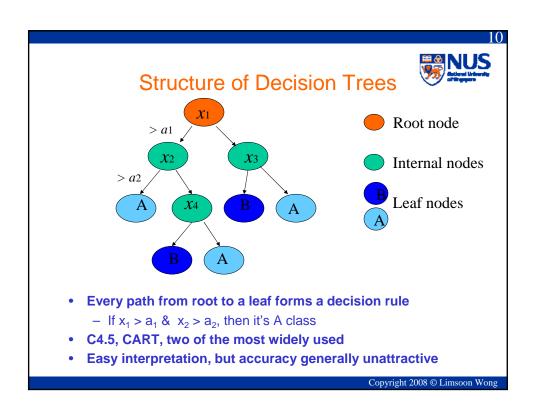

Requirements of Biomedical Classification

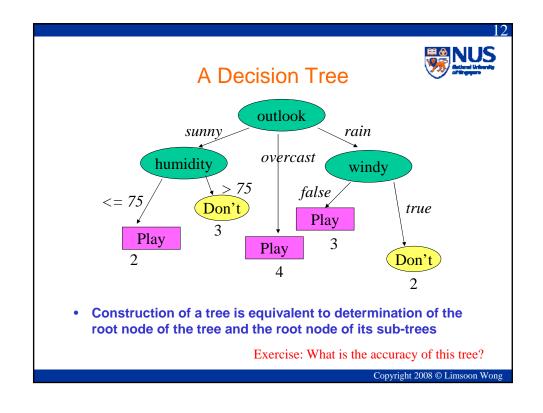

- High accuracy/sensitivity/specificity/precision
- High comprehensibility

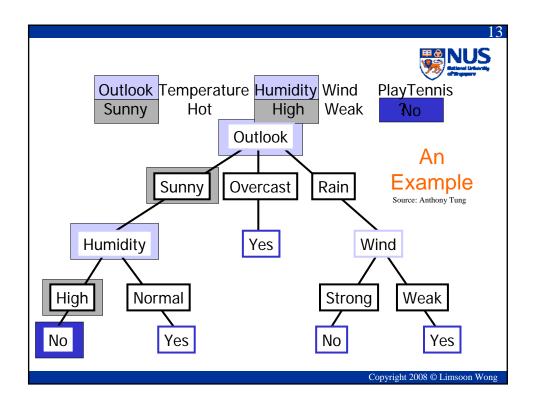

Importance of Rule-Based Method

- Systematic selection of a small number of features used for the decision making
- ⇒ Increase the comprehensibility of the knowledge patterns
- C4.5 and CART are two commonly used rule induction algorithms---a.k.a. decision tree induction algorithms

Rain	70	96	false	Play	

Most Discriminatory Feature

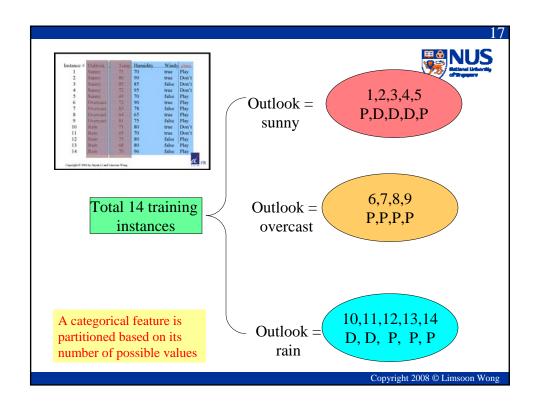

- Every feature can be used to partition the training data
- If the partitions contain a pure class of training instances, then this feature is most discriminatory

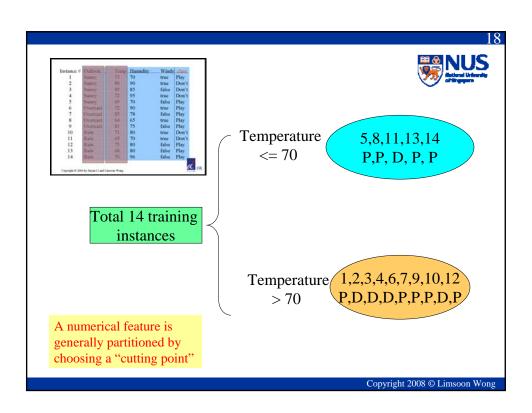

Example of Partitions

- Categorical feature
 - Number of partitions of the training data is equal to the number of values of this feature
- Numerical feature
 - Two partitions

Steps of Decision Tree Construction

- Select the "best" feature as the root node of the whole tree
- Partition the dataset into subsets using this feature so that the subsets are as "pure" as possible
- After partition by this feature, select the best feature (wrt the subset of training data) as the root node of this sub-tree
- Recursively, until the partitions become pure or almost pure

20

Measures to Evaluate Which Feature is Best

- Gini index
- Information gain
- Information gain ratio
- T-statistics
- χ2
- ...

Gini Index

Let $\mathcal{U}=\{C_1,...,C_k\}$ be all the classes. Suppose we are currently at a node and D is the set of those samples that have been moved to this node. Let f be a feature and d[f] be the value of the feature f in a sample d. Let S be a range of values that the feature f can take. Then the Gini index for f in D for the range S is defined as

$$gini_f^D(S) = 1 - \sum_{C_i \in \mathcal{U}} \left(\frac{|\{d \in D \mid d \in C_i, \ d[f] \in S\}|}{|D|} \right)^2$$

The purity of a split of the value range S of an attribute f by some split-point into subranges S_1 and S_2 is then defined as

$$gini_f^D(S_1,S_2) = \sum_{S \in \{S_1,S_2\}} \frac{|\{d \in D \mid d[f] \in S\}|}{|D|} * gini_f^D(S)$$

we choose the feature f and the split-point p that minimizes $gini_f^D(S_1, S_2)$ over all possible alternative features and split-points.

Gini index can be thought of as the expected value of the ratio of the diff of two arbitrary specimens to the mean value of all specimens. Thus the closer it is to 1, the closer you are to the expected "background distribution" of that feature. Conversely, the closer it is to 0, the more "unexpected" the feature is.

Copyright 2008 © Limsoon Wong

$$gini(S) = \frac{\text{diff of two arbitrary specimen in S}}{\text{mean specimen in S}}$$

 $= \frac{prob(getting\ two\ specimen\ of\ diff\ class\ in\ S)}{prob(getting\ specimen\ of\ same\ class\ in\ S)}$

 $\sum_{i \neq j} prob(\text{getting specimen of class } i \text{ in } S) * prob(\text{getting specimen of class } j \text{ in } S)$

$$1 - \sum prob(getting\ specimen\ of\ class\ i\ in\ S)^2$$

$$=1-\sum_{C_i\in\mathcal{U}}\left(\frac{|\{d\in D\mid d\in C_i,\ d[f]\in S\}|}{|D|}\right)^2$$

Gini index can be thought of as the expected value of the ratio of the diff of two arbitrary specimens to the mean value of all specimens. Thus the closer it is to 1, the closer you are to the expected "background distribution" of that feature. Conversely, the closer it is to 0, the more "unexpected" the feature is.

Information Gain

the difference between the information needed to identify the class of a sample in $\mathcal U$ before and after the value of the feature f is revealed is

$$Gain(f, \mathcal{U}, S_1, S_2) = Ent(f, \mathcal{U}, S_1 \cup S_2) - E(f, \mathcal{U}, \{S_1, S_2\})$$

where

• $Ent(f, \mathcal{U}, S)$ is the class entropy of a range S with respect to a feature f and a collection of classes \mathcal{U} . It is defined as

$$Ent(f,\mathcal{U},S) = -\sum_{C_i \in \mathcal{U}} \frac{|\{d \in C_i \mid d[f] \in S\}|}{|\{d \in \bigcup \mathcal{U} \mid d[f] \in S\}|} * \log_2 \left(\frac{|\{d \in C_i \mid d[f] \in S\}|}{|\{d \in \bigcup \mathcal{U} \mid d[f] \in S\}|} \right)$$

• $E(f, \mathcal{U}, \{S_1, S_2\})$ is the class information entropy of the partition (S_1, S_2) . It is defined as

The more partitions S has the bigger this sum is

$$E(f, \mathcal{U}, S) = \sum_{S_i \in S} \frac{|\{d \in \mathcal{U} \mid d[f] \in S_i\}|}{|\{d \in \mathcal{U} \mid d[f] \in \bigcup S\}|} * Ent(f, \mathcal{U}, S_i)$$

Then the information gain is the amount of information that is gained by looking at the value of the feature f, and is defined as

 $InfoGain(f,\mathcal{U}) = \max\{Gain(f,\mathcal{U},S_1,S_2) \mid (S_1,S_2) \text{ is a partitioning of the values of } f \text{ in } \bigcup \mathcal{U} \text{ by some point } T\}$

Copyright 2008 © Limsoon Wong

24

Information Gain Ratio

$$GainRatio(f, \mathcal{U}, S_1, S_2) = \frac{Gain(f, \mathcal{U}, S_1, S_2)}{SplitInfo(f, \mathcal{U}, S_1, S_2)}$$

where $SplitInfo(f, \mathcal{U}, S_1, S_2) = Ent(f, \{\mathcal{U}_f^{S_1}, \mathcal{U}_f^{S_2}\}, S_1 \cup S_2)$, and $\mathcal{U}_f^S = \bigcup_{C_i \in \mathcal{U}} \{d \in C_i \mid d[f] \in S\}$. Then the information gain ratio is defined as

 $\begin{array}{l} \textit{InfoGainRatio}(f,\mathcal{U}) = \max\{GainRatio(f,\mathcal{U},S_1,S_2) \mid (S_1,S_2) \text{ is a partitioning} \\ \text{of the values of } f \text{ in } \bigcup \mathcal{U} \text{ by some point } T\} \end{array}$

Decision Tree Ensembles

Motivating Example

- h₁, h₂, h₃ are indep classifiers w/ accuracy = 60%
- C₁, C₂ are the only classes
- t is a test instance in C₁
- $h(t) = argmax_{C \in \{C1,C2\}} | \{h_j \in \{h_1, h_2, h_3\} | h_j(t) = C\} |$
- Then prob(h(t) = C_1)

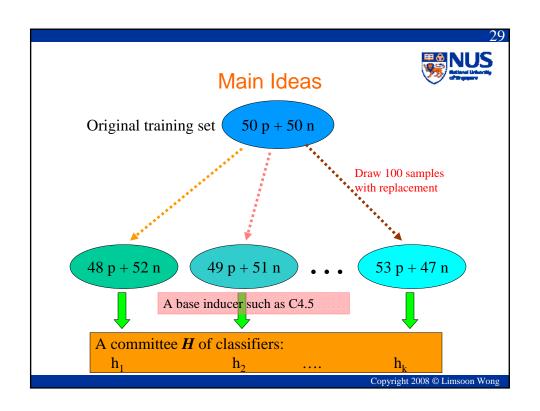

```
= prob(h_1(t)=C_1 \& h_2(t)=C_1 \& h_3(t)=C_1) + prob(h_1(t)=C_1 \& h_2(t)=C_1 \& h_3(t)=C_2) + prob(h_1(t)=C_1 \& h_2(t)=C_2 \& h_3(t)=C_1) + prob(h_1(t)=C_2 \& h_2(t)=C_1 \& h_3(t)=C_1) = 60\% * 60\% * 60\% + 60\% * 60\% * 40\% + 60\% * 40\% + 60\% * 60\% * 60\% = 64.8\%
```

28

Bagging

- Proposed by Breiman (1996)
- Also called Bootstrap aggregating
- Make use of randomness injected to training data

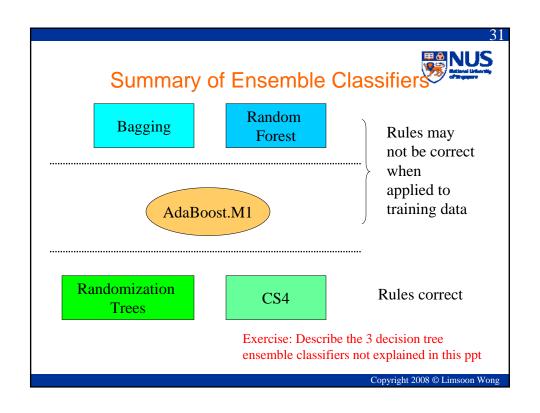

Decision Making by Bagging

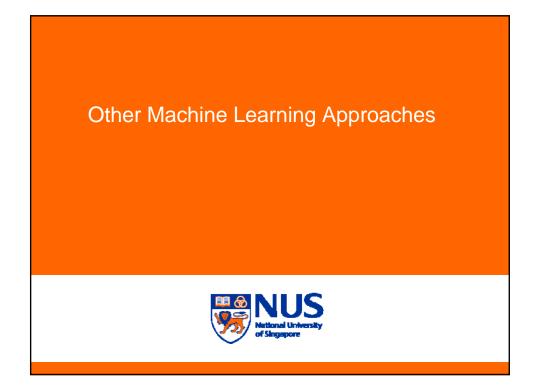

Given a new test sample T

$$bagged(T) = \operatorname{argmax}_{C_j \in \mathcal{U}} |\{h_i \in \mathcal{H} \mid h_i(T) = C_j\}|$$
 where $\mathcal{U} = \{C_1, ..., C_r\}$

Exercise: What does the above formula mean?

Outline

- K-Nearest Neighbour
- Bayesian Approach

Exercise: Name and describe one other commonly used machine learning method

Copyright 2008 © Limsoon Wong

K-Nearest Neighbours

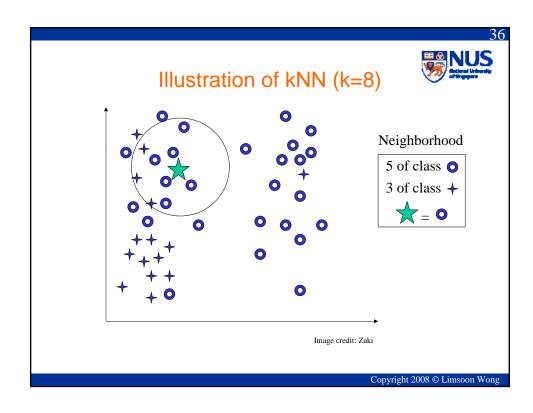

How kNN Works

- Given a new case
- Find k "nearest" neighbours, i.e., k most similar points in the training data set
- Assign new case to the same class to which most of these neighbours belong
- A common "distance" measure betw samples x and y is

$$\sqrt{\sum_f (x[f] - y[f])^2}$$

where f ranges over features of the samples

Exercise: What does the formula above mean?

Some Issues

- Simple to implement
- But need to compare new case against all training cases
- ⇒ May be slow during prediction
- · No need to train
- But need to design distance measure properly
- \Rightarrow may need expert for this
- Can't explain prediction outcome
- ⇒ Can't provide a model of the data

Copyright 2008 © Limsoon Wong

Bayesian Approach

39

Bayes Theorem

$$P(h|d) = \frac{P(d|h) * P(h)}{P(d)}$$

- P(h) = prior prob that hypothesis h holds
- P(d/h) = prob of observing data d given h holds
- P(h/d) = posterior prob that h holds given observed data d

Copyright 2008 © Limsoon Wong

40

Bayesian Approach

• Let H be all possible classes. Given a test instance w/ feature vector $\{f_1 = v_1, ..., f_n = v_n\}$, the most probable classification is given by

$$\operatorname{argmax}_{h_j \in H} P(h_j | f_1 = v_1, \dots, f_n = v_n)$$

Using Bayes Theorem, rewrites to

$$\operatorname{argmax}_{h_j \in H} \frac{P(f_1 = v_1, \dots, f_n = v_n | h_j) * P(h_j)}{P(f_1 = v_1, \dots, f_n = v_n)}$$

• Since denominator is independent of h_{j} , this simplifies to

$$\mathrm{argmax}_{h_j \in H} P(f_1 = v_1, \dots, f_n = v_n | h_j) * P(h_j)$$

NUS Matternal Differently

Naïve Bayes

- But estimating $P(f_1=v_1, ..., f_n=v_n|h_j)$ accurately may not be feasible unless training data set is sufficiently large
- "Solved" by assuming $f_1, ..., f_n$ are conditionally independent of each other
- Then $\operatorname{argmax}_{h_j \in H} P(f_1 = v_1, \dots, f_n = v_n | h_j) * P(h_j)$

$$= \operatorname{argmax}_{h_j \in H} \prod_i P(f_i = v_i | h_j) * P(h_j)$$

• where $P(h_j)$ and $P(f_i=v_i|h_j)$ can often be estimated reliably from typical training data set

Exercise: How do you estimate $P(h_i)$ and $P(f_i=v_i|h_i)$?

Copyright 2008 © Limsoon Wong

Independence vs Conditional Independence

- Independence: P(A,B) = P(A) * P(B)
- Conditional Independence: P(A,B|C) = P(A|C) * P(B|C)
- Indep does not imply conditional indep
 - Consider tossing a fair coin twice
 - A is event of getting head in 1st toss
 - B is event of getting head in 2nd toss
 - · C is event of getting exactly one head
 - Then A={HT, HH}, B={HH, TH} and C={HT, TH}
 - $P(A,B|C) = P(\{HH\}|C) = 0$
 - $P(A|C) = P(A,C)/P(C) = P({HT})/P(C) = (1/4)/(1/2) = 1/2$
 - Similarly, P(B|C) = 1/2

Concluding Remarks...

What have we learned?

- Decision Trees
- Decision Trees Ensembles
 - Bagging
- Other Methods
 - K-Nearest Neighbour
 - Bayesian Approach

Any Question?

Acknowledgements

• The "indep vs conditional indep" example came from Kwok Pui Choi
