Programming with user-defined effects and effect handlers has many practical use cases involving imperative effects. Additionally, it is natural and powerful to use multi-shot effect handlers for non-deterministic or probabilistic programs that allow backtracking to compute a comprehensive outcome. Existing works for verifying effect handlers are restricted in one of two ways: permitting multi-shot continuations under pure setting or allowing heap manipulation for only one-shot continuations, due to the employed protocol mechanism to model interactions between invoked effects and their handlers.

This work proposes a novel calculus called **Effectful Specification Logic (ESL)** to support unrestricted effect handlers, where zero-/one-/multi-shot continuations can co-exist with imperative effects and higher-order constructs. ESL captures behaviors in stages, and provides precise models to support invoked effects, handlers and continuations. To show its feasibility, we prototype an automated verification system for this novel specification logic, prove its soundness, report on useful case studies, and present experimental results. With this proposal, we have provided an extended specification logic that is capable of modeling arbitrary imperative higher-order programs with algebraic effects and continuation-enabled handlers.

**CCS Concepts:**
- Theory of computation \(\rightarrow\) Logic and verification; Program specifications.

**Additional Key Words and Phrases:** Multi-shot Continuations, Separation Logic, Automated Verification, Effectful Specification Logic

**ACM Reference Format:**

\textbf{1 INTRODUCTION}

User-defined effects and effect handlers are a modular approach for delimited control. They offer the ability to suspend and resume computations, allowing information to be transmitted both ways. More specifically, an effect handler resembles an exception handler, i.e., control is transferred to an enclosing handler when performing an effect. Unlike exception handlers, each effect handler has access to its delimited continuation. By invoking this continuation, the handler can communicate a reply to the suspended computation before resuming its execution.

Designs for effect handler implementations [Bauer and Pretnar 2015; Leijen 2014; Phipps-Costin et al. 2023; Sivaramakrishnan et al. 2021], applications [Kawahara and Kameyama 2020; Leijen 2017; Nguyen et al. 2022], and verification solutions [de Vilhena and Pottier 2021; Song et al. 2022; Timany and Birkedal 2019] diverge upon whether it should be permitted or forbidden to invoke a...
captured continuation more than once. Existing works for verifying effect handlers with resources fall into one of two categories: deal with multi-shot continuations only in a pure setting, or reason about heap-manipulating behaviors for exclusively one-shot continuations. For example, a recently proposed separation logic, Hazel [de Vilhena and Pottier 2021], takes the latter approach, while its extension, Maze [de Vilhena 2022], chooses the former, with a restriction that multiple resumptions cannot involve non-persistent assertions, i.e., heap operations or assertions containing resources.

A conclusion from prior work was “With the traditional separation logic, allowing continuations to be invoked more than once breaks certain fundamental laws of reasoning about programs” [de Vilhena and Pottier 2021]. In short, if a continuation can be resumed twice, then a code block can be entered once and exited twice, which was regarded as problematic, as illustrated by an OCaml example in Fig. 1. The program defines an effect \( \text{Label} \) of integer type, indicating that when resumed, its handler should provide an integer value. Function \( \text{callee} \) initializes a pointer \( x \) with 0 and performs \( \text{Label} \) on line 6. The code after line 6 essentially forms the “continuation of performing \( \text{Label} \)”. Finally, the program returns the resumed value \( \text{ret} \) plus 2. So far, nothing is known about the handler for \( \text{Label} \), and we observe different behaviors of \( \text{callee} \) depending on the specific handler:

- Zero-shot handlers abandon the continuation completely, just like exception handlers;
- One-shot handlers resume the continuation once, and the assertion on line 8 must succeed;
- Multi-shot handlers resume the continuation more than once, so \( x \) could be incremented multiple times; thus, the assertion on line 8 would fail for all but first invocation of the continuation.

To reason about such programs, we propose a novel \( \text{Effectful Specification Logic (ESL)} \) that offers new logic constructs for both effect invocations and their unrestricted handlers, where imperative effects and zero-/one-/multi-shot continuations can co-exist. Our effectful specifications extend pre/post specifications by explicitly supporting: effects as uninterpreted relations, \( \text{try-catch} \) handlers as reducible logic constructs, delimited continuations as lambda-bound relations; and interspersing these with pre/post summaries that may appear before and/or after these logic constructs.

\[
\text{callee}(r_c) = \exists x \cdot \text{ens } x \mapsto 0 ; \quad \text{// Line 5} \\
\exists \text{ret} \cdot \text{Label}(\text{ret}) ; \quad \text{// Line 6} \\
\exists z \cdot \text{req } x \mapsto z \land z+1 = 1 \text{ ens}[r_c] x \mapsto z+1 \land r_c = (\text{ret} + 2) \text{// Lines 7-9}
\]

Fig. 2. ESL Specification for \( \text{callee} \).

A precise ESL specification for \( \text{callee} \) is shown in Fig. 2 using three stages that are separated by logical construct ‘;’ to capture computational sequencing. The first stage for Line 5 captures the spec of code fragment \( \text{let } x = \text{ref } 0 \text{ in } [.] \) where [.] denotes the next evaluation context. We
shall use the notation \textit{code :: sp} to associate each code fragment with its specification. Thus:

\[
(\text{let } x = \text{ref } 0 \text{ in } []) :: \exists x \cdot \text{ens } x \rightarrow 0
\]

Here, the specification at this stage indicates that a heap memory location (represented by a pointer to \(x \rightarrow 0\)) needs to be set, which is performed by the code fragment. Also, local variables are existentially quantified using \(\exists x \cdot P\) whose scope may extend past \(P\) to the end of method’s specification. Line 6 captures the invoked effect \textit{Label}, as denoted by:

\[
(\text{let } \text{ret} = \text{perform Label in } []) :: \exists \text{ret} \cdot \text{Label(\text{ret})}
\]

Here, \textit{Label(ret)} denotes an algebraic effect invocation. Each algebraic effect is denoted by an uninterpreted relation \(E(v^*, r)\), with arguments \(v^*\) and result \(r\). The interpretation of such effects would come from concrete handlers that catches these effects (elaborated later in Sec. 2).

Lines 7-9 summarize the continuation code after \textit{Label} via a pair of pre/post with assertion on Line 8 captured by the precondition \((z+i=1)\). Using \([r_c]\) to capture the result of some post-state, we can thus model this last specification stage precisely using:

\[
(x:=!x+1; \text{ assert } (!x=1); \text{ ret+2}) :: \exists z \cdot \text{req } x \rightarrow z \land z+i=1 \ens [r_c] x \rightarrow z+i \land r_c=(\text{ret+2})
\]

It is also possible to use over-approximation to obtain simpler simplifications, where helpful. For example, if the outcome of \textit{callee} need not be tracked, we can over-approximate the last stage with:

\[
(x:=!x+1; \text{ assert } (!x=1); \text{ ret+2}) :: \exists z \cdot \text{req } x \rightarrow z \land z+i=1 \ens [r_c] x \rightarrow z+1
\]

\textit{ESL} specification is generally more complex than say two-stage pre/post specifications since it allows us to model program codes with algebraic effects more precisely via multiple stages. One key benefit of \textit{ESL} is its ability to delay the interpretation for algebraic effect to callers’ sites where try-catch handlers’ specifications and scope of continuation become known.

2 MAIN CONTRIBUTIONS

With \textit{callee}(r_c) defined, we next write \textit{ESL} specifications for different and representative (zero-/one-/multi-shot) handlers, in Fig. 3, Fig. 4, and Fig. 5, respectively. For simplicity, when handlers’ normal-return clauses are identity functions, i.e., \((λ \ x \rightarrow x)\), we omit them.

To model effect handlers precisely, we employ a new logic construct: \textbf{try} (\(Φ\)) \textbf{catch} \{\(pat_i \rightarrow Φ_i\)\}_{i∈I}, as a logical counterpart of the \textit{match-with} statement – where \(Φ\) is the specification of the try block, and each pair \(\{\text{pat}_i \rightarrow Φ_i\}\) denotes the specification of each handling case. Our algebraic effect handling constructs are always verified modularly, in that each handler declaration is only verified once, and each effect invocation can always be replaced by its already verified handling logic. For convenience, we shall use a context notation \(Φ[r]\) where \(r\) explicitly identifies the final result of specification \(Φ\). Also, \(Φ[\_]\) is a shorthand for \((\exists r \cdot Φ[r])\). As an example, the specification for \textit{zero_shot} could be initially modeled as shown below before it is reduced to its counterpart without the try-catch logic construct:

\[
\text{zero_shot}(r_c) = \text{try } (\exists r \cdot \text{callee}(r)) \text{ catch } \{ \text{Label } k \rightarrow \text{ens}[r_c] r_z=-1 \}
\sim^* \exists x \cdot \text{ens}[r_c] x \rightarrow 0 \land r_z=-1
\]

When suitably instantiated\(^1\), each instance of a \textit{try-catch} logical construct is reducible to a simpler specification without it. For \textit{zero_shot}(r_c), it is reducible to just a pre/post specification, as

\(^1\)An example that is not suitably instantiated will be highlighted later in Sec 3.3.
shown above. To reason about the behavior of a handler, we utilize the code specification \((\text{callee}(r))\) in this case) to obtain the stages up to the invoked effect that we are able to handle, namely:

\[
\exists x, \text{ret} \cdot \text{ens} \ x \mapsto 0 \ ; \ \text{Label}(\text{ret})
\]

and leave the remaining stages to be the specification for the continuation, binding it to \(k\):

\[
k = \lambda (\text{inp}, r_k) \to \exists z \cdot \text{req} \ x \mapsto z \land z+i=1 \ \text{ens}[r_k] \ x \mapsto z+i \land r_k=(\text{inp}+2).
\]

For \(\text{zero}\_\text{shot}\), the continuation was never invoked and its match handler simply returned \(\text{res}=1\) as specified, together with heap state \(x \mapsto 0\) constructed earlier. Returning to \(\text{one}\_\text{shot}\) shown in Fig. 4, its specification can be constructed and reduced as follows:

\[
\text{one}\_\text{shot}(r_o) = \text{try callee(\_)} \ \text{catch} \ {\{\text{Label k} \mapsto k(3, r_o)\}}
\]

\[
\rightsquigarrow \exists x \cdot \text{ens}[r_o] \ x \mapsto 1 \land r_o=5.
\]

The continuation call \((\text{resume} \ k \ 3)\) is initially modelled as an uninterpreted relation \(k(3, r_o)\) that is subsequently interpreted by the handler that catches the \(\text{Label}\) effect. Here, we could simplify \(\text{one}\_\text{shot}\)'s specification to just a pre/post specification, which results in the heap location \(x\) being updated to 1 after the precondition \(\exists z \cdot \text{req} \ x \mapsto z \land z+i=1\) is successfully checked.

\[
\text{multi}\_\text{shot}(r_m) = \text{try callee(\_)} \ \text{catch} \ {\{\text{Label k} \mapsto k(4, \_); k(5, r_m)\}} \ \rightsquigarrow \exists \text{req} \ false
\]

The specification for \(\text{multi}\_\text{shot}\) is reduced to a \(\text{false}\) precondition, because the second time that continuation \(\text{resume}\) would violate its precondition \(\exists z \cdot \text{req} \ x \mapsto z \land z+i=1\), since the heap state after the first time continuation invocation would be \(x \mapsto 1\). As a result, the only safe specification is \(\text{req} \ false\), which forbids this function from ever being (safely) called. As an alternative scenario, the verification of \(\text{multi}\_\text{shot}\) would have succeeded if the assertion in \(\text{callee}\) were weakened from \((!x=1)\) to \((!x \geq 1)\). Under this weaker check, the ESL specification for \(\text{weak}\_\text{callee}\) would have been:

\[
\text{weak}\_\text{callee}(r_c) = \exists x \cdot \text{ens}[r_c] \ x \mapsto 0 \ ; \ \exists \text{ret} \cdot \text{Label}(\text{ret}) ;
\]

\[
\exists z \cdot \text{req} \ x \mapsto z \land z+i \geq 1 \ \text{ens}[r_c] \ x \mapsto z+i \land r_c=(\text{ret}+2) \quad \text{// Lines 5-6}
\]

With this change, our reasoning would simplify the specification for the \(\text{multi}\_\text{shot}\) function to its expected outcome: \(\exists x \cdot \text{ens}[r_m] \ x \mapsto 2 \land r_m=7\). This is possible since the preconditions can now be successfully checked for both continuation calls, \(k(4, \_)\) and \(k(5, r_m)\), with the heap location \(x\) incremented twice before the result \(r_m=7\) of the second \(k\) call be successfully returned.

Unlike prior work [de Vilhena 2022; de Vilhena and Pottier 2021; Soares and Pereira 2023], which is unable to verify programs with \(\text{heap-based}\) continuation for multi-shot handlers, we have briefly shown here that sound reasoning is still achievable with the help of our new logic constructs for

Proc. ACM Program. Lang., Vol. 8, No. ICFP, Article 267. Publication date: August 2024.
effect invocations and try-catch handling. One inherent limitation of the previous solution is its reliance on a Player-Opponent protocol logic to model code leading to the continuation call in the handler as communication between programs and handlers via send/receive commands, and to use another sequence of ghost instructions in reverse-mode to model the code after the continuation call in the handler. This modeling supports heap mutation for only single-shot handlers, and it quickly becomes awkward when facing zero/multi-shot handlers. In contrast, ESL captures behavior in stages, partitioned by invoked effects, which allows continuations to be captured and manipulated symbolically and in a delimited fashion. This allows us to model algebraic effects abstractly and provides a more precise mechanism for effect handlers without imposing restrictions on them.

Although simple, these examples show the capabilities of our proposal: i) ESL allows assertions to materialize as heap-based pre-conditions of captured continuations, lending itself to verifying heap-manipulating multi-shot continuations; ii) ESL naturally models unhandled effects as a relation between input(s) and an output, which is paired with a corresponding outer handler; and iii) we extend automated verification for multi-shot cfffect handlers and heap-manipulating continuations, which cannot be verified by the current state-of-the-art systems. Our contributions are:

(1) **Effectful Specification Logic:** We define the syntax and semantics of ESL, which captures staged specifications of heap-operations and assertions, explicitly revealing unhandled effects together with novel try-catch handlers that are usually reducible.

(2) **Hoare-style Verifier:** Targeting an ML-like language with both imperative higher-order features and algebraic effects, we establish forward rules to compositionally summarize and verify programs’ behaviors. The verification utilizes a back-end entailment checker for ESL.

(3) **The Back-end Checker for ESL:** Our back-end checker proves/disproves the entailments between two normalized ESL formulae. We achieve this with the help of a set of normalization rules and a reduction process for try-catch logic constructs, where possible.

(4) **Implementation and Evaluation:** We prototype our proposed verifier, prove its correctness, report on experimental results, and present various case studies investigating ESL’s capabilities. Our target programs and our implementation are both written in Multicore Ocaml.

3 **ILLUSTRATIVE EXAMPLES**

This section presents a few non-trivial examples to show the core idea and benefits of our approach.

3.1 **Passing Pointers with an Effect Invocation**

Consider the example in Fig. 6, which manipulates two pointers. Line 7 invokes effect $E$ with pointer references $i$ and $j$ as arguments. Then by line 8, we have lost the information on the concrete values of $i$ and $j$, because the handler could modify their contents. Although simple, this example shows why traditional pre/post specifications cannot handle such complex control mechanisms. Our proposed ESL resolves the issue by allowing a new stage after performing $E(i,j,ret)$ which uses two existential variables $x$ and $y$ to denote the values of $i$ and $j$, at the resumed point (Line 8). Moreover, this program may have multi-shot handlers,
and at each resumption, x and y will be replaced by fresh variables. From another perspective, ESL essentially takes “invoking effects” and “resuming continuations” as function calls to support modular verification via staged specifications. This paper shows how to soundly compose such specification stages during both forward reasoning and try-catch reduction.

3.2 Multi-Shot Handler with an Imperative Counter

```ml
let all_results counter n
(* all_results(n, r) = ∃z · req counter → z ∧ n > 0 · ens[r] counter → z + (2^k) ∧ r = 1 *)
match tossN n with
| 1 -> perform Flip
| n -> let r1 = perform Flip in
    let r2 = tossN(n-1) in r1 && r2
let all_results counter n
match tossN n with
| x -> if x then 1 else 0
| effect Flip k ->
    counter := !counter + 1; (* increase the counter *)
    let res1 = resume k true in
    counter := !counter + 1;
    let res2 = resume k false in
    res1 + res2
```

Fig. 7 presents a multi-shot handler for a backtracking computation and increases a mutable `counter` whenever the continuation is resumed. Such uses of multi-shot continuations can be found in search problems [de Vilhena 2022], and simulation for probabilistic programs [Nguyen et al. 2022]. We now show that ESL is able to safely verify mutable states with multi-shot continuations.

The `tossN` function takes an argument n, invokes the effect `Flip` n times, and recursively computes a boolean conjunction of all the resumed results. When handling `Flip`, from line 15, the handler resumes the execution twice, with values `true` and `false` respectively, and before each resumption, it increases the counter by 1. As the specification for function `all_results` shows, given the input counter originally points to z and n greater than 0, our verifier proves that `counter` points to

\[ \mathcal{H}_0 = \{ x \rightarrow \exists r \cdot \text{ens}[r] \ (x \land r = 1) \lor (\neg x \land r = 0) \}, \]

\[ \text{Flip}() k \rightarrow \exists z_1, r_1 \cdot \text{req counter} \rightarrow z_1 \cdot \text{ens counter} \rightarrow z_1 + 1 ; k (\text{true, } r_1) ; \]

\[ \exists z_2, r_2 \cdot \text{req counter} \rightarrow z_2 \cdot \text{ens counter} \rightarrow z_2 + 1 ; k (\text{false, } r_2) ; \text{ens}[r] \ r = r_1 + r_2 \]

\[ \Phi_{\text{inv}}(n, \text{acc}, r) = \exists w \cdot \text{req counter} \rightarrow w \cdot \text{ens}[r] \ \text{counter} \rightarrow w + (2^n) \land (\text{acc} \land r = 1 \lor \neg \text{acc} \land r = 0) \]

\[ \text{try } \exists r \cdot \text{tossN}(n, \text{res}) \# \exists r \cdot \text{ens}[r] \ (\text{acc} \land \text{res}) \land r = 1 \lor \neg (\text{acc} \land \text{res}) \land r = 0 \ \text{catch } \mathcal{H}_0 \sqsubseteq \exists r \cdot \Phi_{\text{inv}}(n, \text{acc}, r) \]

Fig. 8. A Try-Catch Lemma Deployed (highlighted in gray), and its Definition.
by two and explores both the base and inductive cases. For example, taking \( \text{counter} \rightarrow 0 \) and \( n = 2 \) as a concrete state when executing \( \text{all\_results} \), the counter will be indeed updated to 6, i.e., \( 0 + 2^{n+1} - 2 \), since the first \( \text{Flip} \) increments \( \text{counter} \) by two and explores both the \text{true} and \text{false} possibilities. For each of these two possibilities, a subsequent \( \text{Flip} \) in the continuation will each explore two more possibilities; hence, in total, \( \text{counter} \) will be increased six times. As for the return value, it represents the times when all the flips are true; hence, it is always 1.

To symbolically prove \( \text{all\_results}'s \) specification, our verifier summarises the specifications for the handler cases using \( \mathcal{H}_0 \). Due to the use of the recursion, our verifier uses lemmas that could be inductively proven. For this example, we first specify the lemma in Fig. 8. We use the \# operator to mean that the flows after \# had already been handled by the handler, which is explained in detail in Sec. 5.2. This lemma captures the behavior of a try-catch construct using a one state mapping, i.e., \( \Phi_{\text{inv}}(n, \text{acc}, r) \). In particular, \( r \) denotes the integer outcome returned by the normal clause, and the formula "\( \exists r \cdot \text{ens}[r] \cdot \cdots \)" captures a pure continuation occurring after the \text{tossN}(n, \text{res}) call.

\[
\begin{align*}
\text{try} \ &\exists r \cdot \text{tossN}(n, \text{res}) \# \exists r \cdot \text{ens}[r] (\text{acc} \land \text{res}) \land r = 1 \lor \lnot (\text{acc} \land \text{res}) \land r = 0 \ \text{catch} \ \mathcal{H}_0 \quad \text{(When n=1)} \\
\sim &\exists r \cdot \text{ens} n = 1; \text{Flip}(r_1) \# \exists r \cdot \text{ens}[r] (\text{acc} \land \text{res}) \land r = 1 \lor \lnot (\text{acc} \land \text{res}) \land r = 0 \ \text{catch} \ \mathcal{H}_0 \quad \text{[\text{R-Eff-Handle}]} \\
&\sim \exists r \cdot \text{ens} n = 1; \exists w_1 \cdot \text{req} \text{counter} \rightarrow w_1 \ \text{ens} \text{counter} \rightarrow w_1 + 1; \exists r'_1 \cdot \text{ens}[r'_1] (\text{acc} \land \text{true} \land r'_1 = 1 \lor \lnot (\text{acc} \land \text{true}) \land r'_1 = 0); \\
&\quad \exists w_2 \cdot \text{req} \text{counter} \rightarrow w_2 \ \text{ens} \text{counter} \rightarrow w_2 + 1; \exists r'_2 \cdot \text{ens}[r'_2] (\text{acc} \land \text{false} \land r'_2 = 1 \lor \lnot (\text{acc} \land \text{false}) \land r'_2 = 0); \\
&\quad \exists r \cdot \text{ens}[r] = r'_1 + r'_2 \\
&\sim \exists r, w \cdot \text{req} \text{counter} \rightarrow w \ \text{ens}[r] \text{counter} \rightarrow w + 2 \land n = 1 \land (\text{acc} \land r = 1 \lor \lnot \text{acc} \land r = 0) \quad \subseteq \exists r \cdot \Phi_{\text{inv}}(1, \text{acc}, r) \\
\end{align*}
\]

Fig. 9. Proving the Lemma in Fig. 8 (reduction rules are boxed), including the Base and Inductive cases.

Our lemma-proving process unfolds the recursive predicate \( \text{tossN}(n, \text{res}) \), before showing that it can be proven to hold for both the base case (when \( n = 1 \)) and the inductive case (when \( n > 1 \)), shown in Fig. 9. Next, after the try-catch lemma has been proven, it can now be used by the try-catch reduction (cf. Sec. 5.2). As shown in Fig. 10, the rule \[\text{R-Lemma-App}\] reduces the formula into the instantiated (verified) lemma, i.e., \( \Phi_{\text{inv}}(n, \text{true}, r) \). Finally, the entailment checking – denoted by \( \sqsubseteq \) – succeeds, and the verification for the \text{all\_results} function completes.

\[
\begin{align*}
\text{try} \ &\exists r \cdot \text{tossN}(n, \text{res}) ; \text{ens}[r] \ \text{emp} \ \text{catch} \ \mathcal{H}_0 \quad \text{[\text{R-Deep}]} \\
\sim &\exists r \cdot \text{tossN}(n, \text{res}) \# \exists r \cdot \text{ens}[r] (r \land r = 1) \lor (\lnot r \land r = 0) \ \text{catch} \ \mathcal{H}_0 \quad \text{[\text{R-Lemma-App}]} \\
&\sim \exists r \cdot \Phi_{\text{inv}}(n, \text{true}, r) \quad \subseteq \exists r \cdot \text{all\_results}(n, r) \\
\end{align*}
\]

Fig. 10. Try-catch Reduction when Handling \text{tossN}, and the Entailment Generated for Function \text{all\_results}.
Although this example is based on a deep handler and a right recursion, we show that our verification approach with the usage of lemmas can cover other non-trivial cases, such as a deep handler with a left recursion, or a shallow handler with both the right and left recursion, respectively. We demonstrate such examples in Appendix A [TR 2024].

### 3.3 A Higher-Order Function with Unresolved Try-Catch Logic Construct

There are situations when try-catch constructs are not sufficiently instantiated for reduction to occur. An example is the higher-order function `foo` with its corresponding ESL specification, as shown in Fig. 11. Here, the try-catch construct cannot be directly eliminated since its body contains a relation $f(res)$ that is yet to be instantiated. Nevertheless, our verification rules can modularly verify the specification of such functions, due to our adoption of try-catch logic construct.

```plaintext
1 let foo f : int (* foo(f, r) = try (∃res·f(res)) catch { Label k → k(5, r) } *)
2 = match f() with
3 | effect Label k -> resume k 5
4
5 let goo () : int (* goo(r) = ∃x·ens[r] x→0 ∧ r=15 *)
6 = let f = (fun () -> let x = ref 0 in (perform Label) + 10)
7 in foo f
```

Fig. 11. An irreducible try-catch construct in foo and its caller goo

Subsequently, each function call to `foo` may have its unknown argument instantiated (with its summarized specification) which can later facilitate try-catch reduction. An example is function `goo`, which calls `foo` with a lambda argument. As shown in Fig. 12, a specification for `goo` can now be obtained by reducing its instantiated try-catch logic construct. Note that our program verification methodology is modular since we only inline summarised specification rather than code, and always perform modular verification on a per-method basis.

```
goo(r) = ∃f · ens f(res) = (∃x, y·ens x→0 ; Label(y); ens[res] res=y+10) ; foo(f, r)
         ~ try ∃res, x, y·ens x→0 ; Label(y); ens[res] res=y+10 catch { Label k → k(5, r) }
         ~* ∃x · ens[r] x→0 ∧ r=15
```

Fig. 12. Deriving the Specification for Function goo.

### 3.4 Possibility of Adding Nested Hoare Triple for Function-Type Parameters

Our new ESL logic (which will be formally presented in Figure 15) is capable of supporting the full higher-order language. Earlier, we illustrated an example where try-catch reduction could get stuck when unknown function parameter call(s) is present. Nevertheless, ESL can also support nested Hoare triple for its function-type parameters, if desired, which is a traditional way for fully supporting higher-order functions. For the same `foo` example, a user may instead specify:

```
foo(f, r) = req f(res) = Φ₁[res] : Φ₂.
```

where “$f(res)=Φ₁[res]$” is a generalization of the nested Hoare triple which captures an over-approximation of $f$’s behaviors inside `foo`’s precondition. When reasoning with the `goo` method (Fig. 12), we would still have a lambda instantiation, namely:
With this new pre-condition, our verifier (see Sec 6) would now need to check a subsumption:

\[ \exists x, y \cdot \text{ens} \ x \mapsto 0; \ Label(y) ; \ \text{ens}[\text{res}] \ \text{res}=y+10 \]

Using such nested Hoare triple for function-type parameter \( f \), try-catch reduction can now occur inside the \( foo \) method with the help of definition \( \Phi_1 \). To make this example more concrete, let \( \Phi_1[\text{res}] = \exists y \cdot \mathcal{N}_1 ; \ Label(y) ; \ \mathcal{N}_2[\text{res}] \), where \( \mathcal{N}_1 \) and \( \mathcal{N}_2 \) are some arbitrary normal stages (formally defined in Fig. 16). We can then perform try-catch reduction inside method \( foo \) as follows:

\[
\begin{align*}
\text{try} \ & \exists \text{res} \cdot f(\text{res}) \ \text{catch} \ \{ \text{Label} \ k \to k(5, r) \} \\
= & \ \text{try} \ \exists \text{res} \cdot \Phi_1[\text{res}] \ \text{catch} \ \{ \text{Label} \ k \to k(5, r) \} \\
= & \ \text{try} \ \exists \text{res}, y \cdot \mathcal{N}_1 ; \ Label(y) ; \ \mathcal{N}_2[\text{res}] \ \text{catch} \ \{ \text{Label} \ k \to k(5, r) \} \\
\sim^* & \ \exists y \cdot \mathcal{N}_1 ; \ \text{ens} \ y=5 ; \ \mathcal{N}_2[r].
\end{align*}
\]

With this elimination of try-catch construct, our new specification for \( foo \) would be:

\[ \text{foo}(f, r) = \exists \mathcal{N}_1, \mathcal{N}_2 \cdot \text{req} \ f(\text{res}) = (\exists y \cdot \mathcal{N}_1 ; \ Label(y) ; \ \mathcal{N}_2[\text{res}]) ; \ \exists y \cdot \mathcal{N}_1 ; \ \text{ens} \ y=5 ; \ \mathcal{N}_2[r]. \]

However, this new specification for \( foo \) is actually more verbose and also less precise than the specification we provided in Fig. 11. It is less precise as pre-condition “\( \text{req} \ f(\text{res}) = \Phi_1[\text{res}] \)” is stronger than “\( \text{req} \ \text{true} \)” used implicitly in our original ESL specification for \( foo \). In both cases, the full higher-order language features are supported by ESL but with different degrees of precision.

4 TARGET LANGUAGE AND SPECIFICATIONS

In this section, we define the syntax and semantics of the target language. For the ESL specification, we start with a general form, denoted as \( \varphi \), then present its normalized form, denoted as \( \Phi \).

---

Fig. 13. Syntax of the Target Language.
4.1 Syntax of Target Language

We target an ML-like call-by-value, higher-order core language with primitive mutable state and user-defined algebraic effects and handlers, defined in Fig. 13. A program $P$ comprises a list of specifications and an expression $e$, where $*$ superscript denotes a finite, possibly empty list of items. Function definitions are represented using let binding and lambda expressions.

Specifications are try-catch lemmas or predicate definitions. Try-catch lemmas aid inductive proofs for behaviors of handlers, and given lemmas are automatically proved before being applied. Recursively defined predicates, where $g$ occurs in $\Phi$, are explicitly marked with the keyword rec. We use $H_\Phi$ to denote the specification for a handler $H$. The syntax of the specification formulae $\Phi$ is given in Sec. 4.3. Values include constants $c$ (including integers, boolean values, and the unit value $()$), and lambda expressions $(\lambda x^*\rightarrow e) :: \Phi$, which are closures with annotated/inferred specifications. Expressions consist of values, variables, let bindings, conditionals, function application, heap operations, assertions ($P$ is in separation logic, containing a spatial conjunction of heap $\sigma$ and pure $\pi$ formulae, see Figure 15 later) and constructs for performing and handling effects.

The expression $\text{perform} \ E(x)$ invokes effect $E$ (e.g., to read a file) with an argument $x$ (e.g., file’s location), which is analogous to raising an exception: when executed, evaluation is suspended, and control is transferred to the nearest enclosing handler for $E$. While raising an exception aborts a computation, performing an effect suspends it, passing the handler a continuation $k$. The handler can use $k$ to $\text{resume}$ the computation with some result (e.g., the contents of the file), which would be transferred to the suspended computation as the result of the $\text{perform}$ statement.

The construct $\text{match} [\delta] e$ with $H$ wraps the expression $e$ in an effect handler $H$. We use $\delta$ to distinguish shallow and deep handlers: $s$ for shallow handlers and $d$ for deep handlers. A shallow handler serves its purpose at most once: after it has handled one effect, it disappears. A deep handler is persistent: it remains installed (as the topmost frame of the captured continuation [Hillerström and Lindley 2018; Kammar et al. 2013]) to handle any number of raised effects. Each handler consists of a normal return clause $(x \rightarrow e)$, which is used if the expression terminates without any effects, and a set of operation cases $\text{ops}$ handling different effect labels, in which the variable $k$ provides access to the continuation, as a first-class value. This paper provides supports for both types of handlers.

4.2 Operational Semantics of Core Language

We define the operational semantics using a big-step reduction relation $[S, h, e] \longrightarrow [S_1, h_1, R']$ in Fig. 14, denoting from an initial store $S$ and heap $h$, $e$ reduces to some runtime outcome $R'$, changing the store and heap to $S_1$, $h_1$. Each store $S$ is a partial map $\text{var} \rightarrow \text{val}$, where $\text{var}$ is the set of (immutable) program variables and $\text{val}$ is the set of primitive values—the set of values that can occur syntactically, augmented with memory locations $t$ and closures $(\lambda x \rightarrow e, S)$, which are a pair of a lambda expression and a store that gives values to its (immutable) free variables. The heap $h$ is a partial map $\text{loc} \rightarrow \text{val}$. Evaluation results $R'$ take one of the forms given at the top of Fig. 14—they are either a normal return of a primitive value $\text{Norm}(v)$, an occurrence of an unhandled effect $\text{Eff}(E(v), e_k)$ with argument $v$ and continuation $e_k$ (a lambda/closure), or an error $\text{Err}$, which occurs on assertion failure. The inclusion of unhandled effects as an evaluation outcome allows handlers and continuations to be directly expressible in our semantics.

Variables are read from the store, while constants evaluate to themselves. Lambda expressions evaluate to closures, capturing the current store. There are four cases for let, which serves to support recursion and sequence evaluation, depending on whether evaluation of $e_1$ produces a value, an error, or an unhandled effect; evaluation either continues, terminates, or suspends with a continuation. Conditionals are standard, and application of a closure restores its captured store before evaluating it. Next are heap operations and assertion, followed by rules for handling effects.
\[ R' \equiv Norm(v) \mid \text{Eff}(E(v), e_k) \mid \text{Err} \]

\[
\begin{align*}

\end{cases} &\quad &\text{(OP-Match-Err)} \\
[S, h, \text{perform } E(x)] &\rightarrow [S, h, \text{Eff}(E(x), (\lambda y{\rightarrow}y)))] &\quad &\text{(OP-Perform)} \\
\end{align*}
\]

Fig. 14. Big-Step Operational Semantics for Core Language with Algebraic Effects.
In (OP-Ret), if the evaluation of the scrutinee e produces a value, the return clause of the handler is executed. If it produces an effect, there are two cases depending on whether the handler is deep or shallow. In (OP-Shallow), execution continues in the body of the appropriate handler case e_h with two arguments bound: the argument v given when the effect was performed, and the continuation k carried by the effect. The rule for deep handlers (OP-Deep) differs in one crucial way: the continuation k is wrapped with an identical handler, so subsequent effects from the continuation will be handled under the same handler. The next two rules cover handled effects and scrutinees which terminate with errors. Finally, (OP-Perform) is where unhandled effects originate, with an identity continuation that is successively extended by let-bindings.

### 4.3 Syntax of Specification Language

We first define the most general form of ESL, using $\varphi$, in Fig. 4.3.1 to facilitate a simpler semantics model; then define a normalized form of ESL, using $\Phi$, in Fig. 4.3.2, to facilitate more straightforward reasoning, try-catch reduction, and the entailment checking. The soundness of our verifier builds on the fact that every normalized ESL formula has a correspondence in the general format.

#### 4.3.1 General ESL

The syntax of $\varphi$ is shown in Fig. 15. The first two constructs are familiar pre/post specifications, which compactly represent program states. In particular, the ensure construct contains a state $Q$ and explicitly indicates the return variable $r$. Those require and ensure constructs can be composed using sequential composition and disjunction to represent sets of program traces. Existential variables may be used to capture intermediate values which arise along such traces.

Finally, imperative, effectful, and higher-order behavior that is difficult to summarize using pre/post specifications can be modeled by the following three new constructs. They give rise to the idea of stages which stratify traces which can otherwise be compacted into pre/post specifications.

- **Effect constructs** like $E(x, r)$, describe occurrences of unhandled algebraic effects, with arguments $x^*$ and a resumed variable $r$.
- **Predicate constructs** like $g(x^*, r)$, describe calls to higher-order function parameters $g$, whose (algebraic or imperative) effects are, at the point, unknown.
- **Try-catch constructs** like $\text{try}[\phi](\varphi) \text{ catch } \mathcal{H}_\Phi$, describe the state resulting from handling effects occurring in some formula $\varphi$ under a handler whose cases are abstractly specified as $\text{ESL}$ formulae.

\[
\begin{align*}
\text{(ESL)} \quad \varphi & \ ::= \quad \text{req } P \mid \text{ens}[r] \mid \varphi; \varphi \mid \varphi \lor \varphi \mid \exists x^* \cdot \varphi \mid \\
& \quad E(x, r) \mid f(x^*, r) \mid \text{try}[\phi](\varphi) \text{ catch } \mathcal{H}_\Phi \\
\text{(Handle Spec.)} \quad \mathcal{H}_\Phi & \ ::= \quad \{ \text{pat}_i \rightarrow \varphi_i \}_{i=1}^n \\
\text{(Pattern)} \quad \text{pat} & \ ::= \quad x \mid E(x) \mid k \\
\text{(State)} \quad P, Q & \ ::= \quad \exists x^* \cdot \sigma \land \pi \\
\text{(Heap)} \quad \sigma & \ ::= \quad \text{emp} \mid x \mapsto v \mid \sigma_1 \ast \sigma_2 \\
\text{(Terms)} \quad t & \ ::= \quad v \mid t_1 \cdot t_2 \mid t_1 - t_2 \\
\text{(Pure)} \quad \pi & \ ::= \quad \text{true} \mid \text{false} \mid \text{bop}(t_1, t_2) \mid f(x^*, r) = \varphi \mid \pi_1 \land \pi_2 \mid \pi_1 \lor \pi_2 \mid \neg \pi \mid \exists x \cdot \pi
\end{align*}
\]

Fig. 15. Syntax of General ESL (Effectful Specification Logic).

We describe program states using separation logic formulae $\sigma$ from the symbolic heap fragment, which can be: a predicate emp, which models an empty heap; singleton heap predicates $x \mapsto v$, which describes a location in memory pointed to $v$ by $x$; formula $x \mapsto _-$, which means that $x$ is allocated; separating conjunction $\sigma_1 \ast \sigma_2$, and existential quantification over values (including locations). We use $\pi$ to denote pure formulae, which capture arithmetic and boolean constraints on
program variables, as well as definitions of staged specifications for functions. Binary relations \( bop(t_1, t_2) \) include \( =, >, <, \geq \) and \( \leq \). Terms are values or additions/subtractions of terms.

\[
\begin{align*}
(ESL) & \quad \Phi \ ::= \theta \mid \Phi \lor \Phi \\
(Staged Flow) & \quad \theta \ ::= \mathcal{E}^* ; \mathcal{N} \\
(Effect/Pred./TryCatch Stages) & \quad \mathcal{E} \ ::= \mathcal{N} ; O \\
(Uninterpreted Predicates) & \quad O \ ::= E(x, r) \mid g(x^*, r) \mid \text{try}[\delta](\Phi) \text{ catch } \mathcal{H}_\Phi \\
(Normal Stage) & \quad \mathcal{N} \ ::= \exists x^* \cdot \text{req P ens Q}
\end{align*}
\]

Fig. 16. Syntax of Normalized ESL.

4.3.2 Normalized ESL. In most of this paper, we focus on ESL formulae occurring in a more structured form \( \Phi \), shown in Fig. 16. The rules of Sec. 5.1 operate on and maintain this form, and additional normalization steps for it are covered in Sec. 5.2. The intuition behind this form is that we would like to reason about straight-line program paths described using staged flows, which are sequences of stages (and thus describe segments in traces). Top-level ESL formulae \( \Phi \) are disjunctions of flows \( \theta \). Staged flows are in the form of \( (\mathcal{E}^* ; \mathcal{N}) \), which contains a prefix of stages \( \mathcal{E}^* \) followed by a final normal stage \( \mathcal{N} \). Each \( \mathcal{E} \) stage contains a normal stage followed by an uninterpreted predicate, \( O \), which indicates unhandled effects, higher-order calls that are not yet instantiated or irreducible try-catch constructs, respectively. For example, an effect stages like \( \mathcal{N} : E(x, r) \), contains a normal stage \( \mathcal{N} \), which describes the state just before the occurrence of an unhandled effect.

Discussion. Traditional separation logic specifications denoted by (\( \text{req P ens Q} \)) can be captured by a single normal stage. Therefore, ESL formulae describe program traces in a compact form, revealing only interesting points along them. This design enables careful specification of effectful and imperative program behaviors. In the next section, we formalize the semantics of ESL formulae.

4.4 Semantic Model of Stages

We assume a standard separation logic models relation \( S, h \models \sigma \land \pi \), which holds iff the state \( S, h \) satisfies the heap formula \( \sigma \land \pi \). Other standard notation for heaps is used: \( \text{dom}(h) \) is the domain of heap \( h \), \( h_1 \cup h_2 = h \) is the disjoint union, i.e., given \( \text{dom}(h_1) \cap \text{dom}(h_2) = \emptyset, h_1 \cup h_2 = h \), \( S_1[\{x:=v\}] \) and \( S_2[\{x\}] \) respectively denote store extension and removal of variables. \( S_1 \bowtie S_2 \) denotes a store merge where bindings in \( S_2 \) take precedence. The same operations apply to heaps, which may additionally be updated, denoted by \( h[\{x:=v\}] \). We write \( h_1 \subseteq h_2 \) to denote that \( h_1 \) is a subheap of \( h_2 \), i.e., \( \exists h_3 \cdot h_1 \bowtie h_3 = h_2 \).

The semantics of a staged formula \( \varphi \) is given as a models relation \( \llbracket C, S, h \rrbracket \sim_m \llbracket C_1, S_1, h_1, R^c \rrbracket \models \varphi \). Since staged formulae describe execution traces, the models relations holds iff in the starting state \( S, h \), if the program described abstractly by \( \varphi \) terminates, it does so in a final state \( S_1, h_1 \) with compile-time (set-based) outcome \( R^c \), which is either of the form \( \text{Norm}(r) \), indicating the normal return of a value via variable \( r \), \( \text{Eff}(E(v, r), \varphi_1) \), indicating an unhandled effect \( E \) with argument \( v \), return variable \( r \) and continuation described by \( \varphi_1 \), or \( \top \), indicating an indeterminate result (that includes \( \text{Err} \) error). \( C \) (resp. \( C_1 \)) is a boolean value that is \( \text{false} (\top) \) iff a precondition failure has possibly occurred prior to (resp. after) the execution of \( \varphi \), otherwise it is \( \text{true} (\top) \). If a precondition failure occurs during the execution of \( \varphi \), the result in the final state becomes indeterminate (\( \top \)), and further execution vacuously succeeds, as shown in the first rule in Fig. 17.

The meaning of \( \text{req} \ \sigma \land \pi \) is given by the next two rules: it requires a heaplet \( h_2 \) satisfying \( \sigma \land \pi \) to be part of the initial heap \( h \) and removes it, analogous to a standard separation logic precondition.
[X, h] \leadsto_m [X, h, τ] \models \varphi \quad R^C := \text{Norm}(r) \mid \text{Eff}(E(r, \varphi)) \mid τ

[✓, h] \leadsto_m [✓, h, \text{Norm(\_)}] \models \text{req} \sigma \land \pi

[✓, h] \leadsto_m [X, h, τ] \models \text{req} \sigma \land \pi

[✓, h] \leadsto_m [✓, \text{hoh}_2, \text{Norm(r)}] \models \text{ens}[r] \sigma \land \pi

[✓, S_k] \leadsto_m [✓, S_k, h_2] \models \text{try}[d](\varphi_2) \text{ catch } \mathcal{H}_φ \models [r_c]

Fig. 17. Semantics of Staged Formulae with Effects and Try-Catch Handlers.
If there is no such heaplet, a precondition failure occurs. \( \text{ens } \sigma \land \pi \) plays a dual role, creating a heaplet \( h_2 \). Like the cases for \textit{let} in the operational semantics, there are three cases for sequencing depending on whether the first formula results in a value, effect, or error, with errors propagating via precondition failures. Disjunction chooses between one of two flows and ensures that precondition failure \textit{cannot occur if both} \( C_1 \) and \( C_2 \) have \textit{no} precondition failures. Existentials add variables to the store with existential values; “reading” of these variables from the store occurs via the separation logic \textit{models} relation. The semantics of predicate stages is simply that of the function they stand for. As we define the operational semantics, it is reasonable to expect that to execute programs, they must be \textit{closed}, and predicate stages refer to functions defined in the program. The remaining cases handle effect stages. Like the case for \textit{perform} in the operational semantics, an effect stage occurring on its own is unhandled, resulting in an unhandled effect with an identity continuation, represented as a trivial staged formula. The rules for \textit{try} cover the cases where the scrutinee staged formula fails or produces an unhandled effect, a result, or a handled effect under a shallow or deep handler, in order. They are largely similar to the operational semantics, as the \textit{try–catch} construct is a direct symbolic analogue of the \textit{match–with} statement.

5 FORWARD VERIFICATION

![Fig. 18. System Overview](image)

Fig. 18 presents an overview of our automated verification system. Our main technical contributions are captured in the rounded boxes: a Hoare-style forward verifier, a reduction for try-catch constructs and an entailment checker. The input of the forward verifier is a target program \( P \), and its functions are annotated with the ESL specifications \( \Phi \). The input of the entailment checking is a pair of ESL formulae: LHS and RHS, referring to the entailment LHS \( \sqsubseteq \) RHS to be checked (LHS and RHS refer to left/right-hand-side effects respectively). The ESL entailment relation \( \sqsubseteq \) is formally defined in Sec. 6. The workflow of our automated verification system is as follows:

1. The forward verifier takes a program \( P \), which contains a set of functions annotated with specifications \( \Phi \), and predefined lemmas. For each function, a modular verification – where functions can be replaced by their already-verified specifications – computes the actual behaviors of the function body, denoted by \( \Phi_{\text{actual}} \), using a set of forward rules, defined in Sec. 5.1.

2. The forward verifier employs a set of reduction and normalization rules, defined in Sec. 5.2, to eliminate try-catch logic constructs when possible.

3. Taking \( \Phi_{\text{actual}} \) and \( \Phi \), the back-end checker proves/disproves the entailment \( \Phi_{\text{actual}} \sqsubseteq \Phi \). We establish a set of entailment rules in Sec. 6. Separation logic proof obligations are reduced [Chin et al. 2011; Piskac et al. 2013] to decidable first-order theory that fits well into the satisfiability modulo theories (SMT) framework. We explain the entailment checking in Sec. 6.

Next, we elaborate on the forward reasoning rules in Sec. 5.1, the try-catch reduction in Sec. 5.2, and present the soundness proofs in Sec. 5.3.
5.1 Forward Verification Rules

We formalize a set of syntax-directed forward rules for the target language. The forward reasoning is in the form of Hoare-style triples: \( \{ N \} e \{ \Phi \} \). Under a partial correctness interpretation, which we adopt in this paper, the triple means that if \( N \) describes the latest normal stage before executing \( e \), if \( e \) terminates, \( \Phi \) describes the staged flows that will be triggered after. The verification is initialized with a fresh normal stage, i.e., \( \text{ens emp} \), as a short-hand for \( \text{req emp ens}[\_ \_ \_ \_] \text{ emp} \).

![Formal rules](image)

Fig. 19. Hoare-style Forward Reasoning Rules
We present key forward Hoare-style reasoning rules in Fig. 19. Three structural rules are first shown to handle the frames on the history flows (\(\text{[FV-Frame]}\)), existential variables (\(\text{[FV-Ex]}\)), and the disjunctions on the starting program state (\(\text{[FV-Disj]}\)).

Rule \([\text{FV-Var-Const}]\) tracks the result \(r\) of latest program state by binding it to a value \(v\), which can be either a variable or a constant. Rule \([\text{FV-Let}]\) firstly reasons about \(e_1\) and generates an existential variable \(x\), then binds \(x\) to the result value of \(e_1\) in its last normal stage and continues to compute the staged flows of the rest of the code. The final state of such sequencing is to concatenate the history flows of \(e_1\) and the flows generated from \(e_2\).

Rule \([\text{FV-Perform}]\) models each effect as a predicate with an existential result \(r\). As shown in the rule \([\text{FV-Lambda-Def}]\), given any lambda definition with a specification \(\Phi[r]\), modular verification starts by computing the actual behavior of the function body, denoted by \(\exists r' \cdot \Phi'[r']\), and check whether it entails its specifications. If the entailment succeeds, the rule binds its specification to a freshly created existential name \(f\). As function specifications are pure, they can be accumulated as pure constraints, denoted using \(\text{Pure}(Q)\). Rule \([\text{FV-If-Else}]\) computes the staged flows from both branches by extending the state with \(v\) bound to \(true\) and \(false\), respectively; then, it disjunctively unions the results. Here, we write \(N \land \pi\) to mean \((\exists x^* \cdot \text{req } P \ens Q \land \pi)\), if \((N = \exists x^* \cdot \text{req } P \ens Q)\).

Rule \([\text{FV-Pred}]\) concatenates the instantiated specification for the callee function \(f\) to the current state. In cases where the predicate is recursively defined, the rule \([\text{FV-Rec-Pred}]\) instantiates the predicate without unfolding the definition. In cases where \(f\) is unknown in the current program, the rule \([\text{FV-Call-Unknown}]\) extends the program state with an uninterpreted predicate.

\([\text{FV-Match}]\) computes the staged flows of \(e\), denoted as \(\Phi\); integrates the handler’s specification, denoted as \(\mathcal{H}_d\); then it employs reduction rules to eliminate the try-catch construct. We elaborate on the reduction for handlers in Sec. 5.2. Here, \(\text{Pure}(\Phi)\) is meant to propagate the pure information accumulated from the staged flow \(\Phi\).

\([\text{FV-Assert}], \text{[FV-Write]}, \text{[FV-Read]}\), and \([\text{FV-Ref}]\) make use of a bi-abduction operator \(\triangleright_{\text{Bi-ab}}\), and propagate the \text{anti-frame} to the precondition and update the postcondition based on the \text{frame}.

\textbf{Bi-abduction.} Bi-abduction is a form of logical inference for separation logic to support automated heap-based local reasoning. Usually, an entailment for separation logic like \(P \triangleright_{\text{sl}} Q\) means that \(P\) implies \(Q\). A challenge is for the theorem prover to discover a pair of \text{frame} and \text{anti-frame} formulae that make the entailment valid. The inference of the frame \(Q_e\) and anti-frame \(P_A\) in a bi-abduction relation \((P_\ast ? P_A \triangleright_{\text{Bi-ab}} Q_\ast ? Q_F)\) is now well-understood [Calcagno et al. 2009].
An example of the forward reasoning. Fig. 20 sketches the steps of verifying the callee function (defined in Fig. 1). Program behavior is captured in the form of \( \{ \Phi \} \). We label the steps from (1) to (7) and mark the applied forward rules in [gray].

The initial state in step (1) and the entailment checking in step (7) are obtained by the rule \([FV\text{-}Fun]\). The state in step (4) is obtained by applying the rules \([FV\text{-}Read]\) and \([FV\text{-}Write]\) in sequence. At step (6), we obtained the actual behaviors \( \Phi_{\text{actual}} \) of callee, which can be normalized into one effect-flow followed by one normal-flow, namely \( \Phi_{\text{actual}}(r') = \cal{E} ; N \), where,

\[ \cal{E} = \exists x, \text{ret} \cdot \text{ens} x \rightarrow 0 ; \text{Label} (\text{ret}) \quad \text{and} \quad N = \exists z \cdot \text{req} x \rightarrow z \land z+1 \equiv \text{ens}[r'] x \rightarrow z+1 \land r' = \text{ret}+2. \]

Deployed normalisation rules. Fig. 21 presents the normalization rules that are used during the reasoning and keep the program states always in a normalized form.

\[
\frac{[N\text{-Norm-Disj}]}{(N; \Phi_1) \leftarrow \Phi'_1 \quad (N; \Phi_2) \leftarrow \Phi'_2} \quad \frac{[N\text{-Norm-Flow}]}{\theta = N' ; \theta' \quad N'' \leftarrow N; N'}
\]

\[
N = \exists x^* \cdot \text{req} P \text{ens} Q \\
N' = \exists y^* \cdot \text{req} P' \text{ens} Q' \\
Q * \text{？} P_A +_{\text{Bi-ab}} P' * \text{？} Q_F \quad N'' = \exists x^*, y^* \cdot \text{req} P * P_A \text{ens} Q' * Q_F \\
N'' \leftarrow N''
\]

Fig. 21. Deployed Normalization Rules.

5.2 Reduction of Try-Catch Constructs

Given any handler type \( \delta \), any ESL formula \( \Phi \), and any handler specification \( \mathcal{H}_\Phi \), the relation \((\text{try}[\delta](\Phi) \text{ catch } \mathcal{H}_\Phi \leadsto \Phi')\) holds if after \( \Phi \) is handled by \( \mathcal{H}_\Phi \), the staged flows result to \( \Phi' \). All the disjunction within the try-block are reduced independently, by \([\mathcal{R}\text{-Disj}]\), shown as follows:

\[
\text{try}[\delta](\Phi_1 \lor \Phi_2) \text{ catch } \mathcal{H}_\Phi = \text{try}[\delta](\Phi_1) \text{ catch } \mathcal{H}_\Phi \lor \text{try}[\delta](\Phi_2) \text{ catch } \mathcal{H}_\Phi \quad [\mathcal{R}\text{-Disj}]
\]

The complete set of try-catch reduction rules is given in Fig. 22. We assume that the specification of the try-block is in a normalized form, i.e., \((\theta = \cal{E}^* ; N)\), and the nested handlers are reduced before hand, if possible; otherwise, they would be left as irreducible.

Rule \([\mathcal{R}\text{-Normal}]\) denotes the base case, which is applied when there is a normal stage \( N \) and returns \( r \), indicating the execution of the handled program has finished. In this case, the resulting staged flows are achieved by composing \( N \) with the instantiated specification of the normal clause. This step corresponds to the operational semantics rule \((OP\text{-Ret})\) in Fig. 14. Rule \([\mathcal{R}\text{-Skip}]\) is applied when the starting flow is an effect stage \( \cal{E} \), which the current handler cannot handle, corresponding to \((OP\text{-Unhandled})\). In this case, it adds \( \cal{E} \) into the history and continues to reason about the rest of the flow. Rule \([\mathcal{H}\text{-Unfold}]\) unfolds the non-recursive definition of a higher-order stage. In cases where \( f \) is unknown (cf. the example in Sec. 3.3), the try-catch construct is left as irreducible at this moment and the reduction resumes whenever \( f \) is suitably instantiated.

Before actually handling any effects, we first reason about the behaviors of its continuation so that when later needed, we could instantiate the high-order predicate \( k \) using the continuation’s specification. Thus, we introduce a new intermediate try-catch logic construct of the form
(\(x \to \Phi_n\) \(\in \mathcal{H}_\Phi\))
\[
\text{try}[\delta](\mathcal{N}[r]) \text{ catch } \mathcal{H}_\Phi \leadsto \mathcal{N}[r]; \Phi_n[r/x]\]  
\[\text{[R-Normal]}\]

\(\mathcal{E} = \mathcal{N}; \ E(x, r) \ E \notin \text{dom}(\mathcal{H}_\Phi)\)
\[
\text{try}[\delta](\mathcal{E}; \ \emptyset) \text{ catch } \mathcal{H}_\Phi \leadsto \mathcal{E}; \ \text{try}[\delta](\emptyset) \text{ catch } \mathcal{H}_\Phi\]
\[\text{[R-Skip]}\]

\(\mathcal{E} = \mathcal{N}; \ f(x', r') (f(y', r) = \Phi_f) \in \mathcal{P}\)
\[
\text{try}[\delta](\mathcal{E}; \ \emptyset) \text{ catch } \mathcal{H}_\Phi \leadsto \text{try}[\delta](\mathcal{N}; \ \Phi_f[x'/y', r'/r]; \ \emptyset) \text{ catch } \mathcal{H}_\Phi\]
\[\text{[R-Unfold]}\]

\(\mathcal{E} = \mathcal{N}; \ E(x, r) \ E \in \text{dom}(\mathcal{H}_\Phi) (x' \to \Phi_n) \in \mathcal{H}_\Phi \ \Phi = \emptyset[r_1]; \Phi_n[r_1/x']\)
\[
\text{try}[s](\mathcal{E}; \ \emptyset) \text{ catch } \mathcal{H}_\Phi \leadsto \text{try}[s](\mathcal{E} \# \Phi) \text{ catch } \mathcal{H}_\Phi\]
\[\text{[R-Shallow]}\]

\(\mathcal{E} = \mathcal{N}; \ E(x, r) \ E \in \text{dom}(\mathcal{H}_\Phi) \Phi' = \Phi[x/y, (\lambda(r, r_c) \to \Phi[r_c])/k]\)
\[
\text{try}[\delta](\mathcal{E} \# \Phi[r_c]) \text{ catch } \mathcal{H}_\Phi \leadsto \mathcal{N}; \ \Phi'\]
\[\text{[R-Eff-Handle]}\]

\(\mathcal{E} = \mathcal{N}; \ f(x', r') (\text{rec } f(y', r) = \Phi_f) \in \mathcal{P} \ \text{fst}(\Phi_f) \in \text{dom}(\mathcal{H}_\Phi)\)
\[
\text{try}[\delta](f(y', r) \ # \Phi) \text{ catch } \mathcal{H}_\Phi \subseteq \Phi_{\text{inv}} \in \mathcal{P}\]
\[
\text{try}[\delta](\mathcal{E} \# \Phi_c) \text{ catch } \mathcal{H}_\Phi \leadsto \mathcal{N}; \ \Phi_{\text{inv}}[x'/y', r'/r, \Phi_c/\Phi]\]
\[\text{[R-Lemma-App]}\]

Fig. 22. Reduction Rules for Try-Catch Constructs

\((\text{try}[\delta](\mathcal{E} \# \Phi_c) \text{ catch } \mathcal{H}_\Phi)\) where \(\mathcal{E}\) is the current effect stage, and \(\Phi_c\) is the reduced specification for \(\mathcal{E}\)’s continuation with respect to the definition of \(\mathcal{H}_\Phi\), formally defined in Fig. 23.

With that, we distinguish the reasoning of the deep and shallow handlers. Rule [R-Shallow] handles the continuation using the normal clause of \(\mathcal{H}_\Phi\), corresponding to our semantics of shallow handlers (OP-Shallow), which are only installed for the first effect and the final normal return, and inserts a # marker between the current effect stage and the handled continuation, i.e., \(\Phi\). Whereas [R-Deep] reasons about the continuation using \(\mathcal{H}_\Phi\) unchanged, corresponding to the semantics of deep handlers (OP-Deep), which are persistently installed. After the continuations are properly

\([\checkmark, S, h] \leadsto_m [C, S_1, h_1, R] \quad \text{iff} \quad \mathcal{E} = \mathcal{N}; \ E(x, r) \ (E(y)k \to \varphi_1) \in \mathcal{H}_\Phi\)
\[
\text{[Try-Catch Construct]}\]

Fig. 23. The Semantics of the # Try-Catch Construct
handled, rule \([\mathcal{R}\text{-}Handle]\) handles the current effect by instantiating the arguments and bind \(k\) using a lambda specification constructed using the specification for the continuation.

A try-catch lemma of a try-catch construct is in the form \((\text{try}[\delta](f(y', r) \neq \Phi) \text{ catch } \mathcal{H}_\Phi = \Phi_{\text{inv}})\) where \(f\) is recursively defined and \(\Phi\) is the specification for the already handled continuation. Rule \([\mathcal{R}\text{-}Lemma\text{-}App]\) firstly retrieves the lemma definition and reduces the current try-catch construct to the instantiated summary, i.e., \(\Phi_{\text{inv}}[x'/y', r'/r, \Phi_\delta/\Phi]\). Note that the side condition requires that the first possible effect generated by \(f\) must be handled by the current handler, expressed as \("\text{fst}(\Phi_f) \in \text{dom}(\mathcal{H}_\Phi)\". Otherwise, \([\mathcal{R}\text{-}Unfold]\) and \([\mathcal{R}\text{-}Skip]\) shall be applied before hand.

Theorem 5.1 defines the soundness of the try-catch reduction process. Moreover, the reduction always terminates successfully if sufficient lemmas are given and proven; otherwise, it can be left as irreducible when there are unknown predicates or lemmas. Termination of the try-catch reduction rules theselves can be proven with the help of the following decreasing measure.

\[
M[\text{try}(\Phi_1; \Phi_2)\text{ catch } H] < M[\text{try}(\Phi_1; \Phi_2)\text{ catch } H] \\
M[\text{try}(\Phi_2)\text{ catch } H] < M[\text{try}(\Phi_1; \Phi_2)\text{ catch } H] \\
M[\text{try}(\Phi_1; \text{ unfold}(f(x')); \Phi_2)\text{ catch } H] < M[\text{try}(\Phi_1; f(x'); \Phi_2)\text{ catch } H], \text{if } f \text{ is non-recursive} \\
M[\Phi_1] < M[\Phi_2], \text{if } \Phi_1 \text{ is a sub-term of } \Phi_2
\]

Discussion. Note that the induction principle applies to both deep and shallow handlers in a unified manner, which supports arbitrary recursive calls without restricting to one-shot continuations. We demonstrate the applicability using a left recursive toss function in both deep and shallow handlers in Appendix A [TR 2024]. To the author’s knowledge, this cannot be achieved by prior works.

5.3 Soundness Proofs

Theorem 5.1 (Soundness of Reduction). Given any try-catch reduction, \(\text{try}[\delta](\Phi) \text{ catch } \mathcal{H}_\Phi \leadsto \Phi'\); for all \(S, h, C_1, S_1, h_1, \) and \(R_1\), if \([\check{\vee}, S, h] \leadsto_m [C_1, S_1, h_1, R_1] \models \text{try}[\delta](\Phi) \text{ catch } \mathcal{H}_\Phi\), then \([\check{\vee}, S, h] \leadsto_m [C_1, S_1, h_1, R_1] \models \Phi'\) holds.

Proof. By induction on the structure of the reduction rule, elaborated in Appendix B.1 [TR 2024].

Theorem 5.2 (Soundness of Normalization). Given any normalization rule, if it concludes that \((\varphi \vdash \Phi); \text{forall } S_0, h_0, C_1, S_1, h_1, \text{ and } R_1, \text{if } [\check{\vee}, S_0, h_0] \leadsto_m [C_1, S_1, h_1, R_1] \models \varphi, \text{then } [\check{\vee}, S_0, h_0] \leadsto_m [C_1, S_1, h_1, R_1] \models \Phi\) holds.

Proof. By induction on the structure of the normalization rule, elaborated in Appendix B.2 [TR 2024].

Theorem 5.3 (Soundness of Forward Rules). If the forward reasoning concludes that a given triple \(\vdash \{N\} e \{\varphi\}\) is valid, for all \(S_0\) and \(h_0\), if \([\check{\vee}, S_0, h_0] \leadsto_m [\check{\vee}, S, h, \text{Norm(\_)}] \models N, \text{and let } \text{SH} = \{S_1, h_1, R_1\} \models [\check{\vee}, S_0, h_0] \leadsto_m [\check{\vee}, S_1, h_1, R_1] \models \Phi, \text{and SH}\#0, \text{then } [S, h, e] \longrightarrow [S_2, h_2, R_2] \land R_2 \neq \text{Err} \land \exists (S_3, h_3, R_3) \in \text{SH} \cdot ([\check{\vee}, S_0, h_0] \leadsto_m [\check{\vee}, S_3, h_3, R_3] \models \Phi \land S_3 \supseteq S_2, h_3 = h_2, R_2 \subseteq R_3).\)

Proof. By induction on the derivation of \([S, h, e] \longrightarrow [S_2, h_2, R_2]\), and the proofs are built on top of Theorem 5.1 and Theorem 5.2. Details are elaborated in Appendix B.3 [TR 2024].
To understand Theorem 5.3, recall that in the triple $\vdash \{ N \} e \{ \Phi \}$, $\Phi$ describes the behavior of $e$ if it is executed in some state following some "historical" execution that ends with $N$. During the verification, as $e$ is traversed, the forward verification rules intuitively transform the history, resulting in a final abstraction of its behavior denoted as $\Phi$. In the statement of the theorem, $S_0, h_0$ is the initial state prior to the execution of the history $N$, which leads to the state $S, h$ in which $e$ will be executed, in turn leading to the state $S_2, h_2, R_2$. The theorem says that given a triple $\vdash \{ N \} e \{ \Phi \}$ whose validity is witnessed by the non-emptiness of the set $e_0$ if it is executed in some state $S$. 6 ENTAILMENT CHECKING

is the residue (as the result of frame inference), both of which are state formulae. The entailment rules

$\Phi$ of the form $P \vdash N$ are a superset of that of $\Phi$ whose validity is witnessed by the non-emptiness of the set $SH$ (which contains the safe final states $S_1, h_1, R_1$, $S_0, h_0$) then the execution of $e$ will result in a (safe) state corresponding to some state $S_3, h_3, R_3$ in $SH$. This correspondence is, concretely, that the final heap should be identical, the final result should be non-erroneous and identical, and the store of $\Phi$ should be a superset of that of $e$ (due to variables arising from staged existentials).

6 ENTAILMENT CHECKING

Given two ESL formulae $\Phi_1$ and $\Phi_2$, this section presents an algorithm for automatically checking the entailment relation $\Phi_1 \subseteq \Phi_2$. Intuitively, proving $\Phi_1 \subseteq \Phi_2$ amounts to checking whether all the possible flows in the antecedent $\Phi_1$ form a subset of all the possible flows in the consequent $\Phi_2$.

$$
\begin{align*}
&\text{[Entail-LHS-OR]} \quad P_A \vdash \Phi_1 \subseteq \Phi \Rightarrow Q^1_F, \quad P_A \vdash \Phi_2 \subseteq \Phi \Rightarrow Q^2_F \\
&\quad \Rightarrow P_A \vdash \Phi_1 \lor \Phi_2 \subseteq \Phi \Rightarrow Q^1_F \lor Q^2_F \\
&\text{[Entail-Unfold-LHS]} \quad g(x', r) = \Phi_1 \in P \\
&\quad \Rightarrow P_A \vdash N_1 ; \Phi_1[y'/x'] [r_1/r] \subseteq \Phi \Rightarrow Q_F \\
&\quad \Rightarrow P_A \vdash N_1 ; g(y', r_1) \subseteq \Phi \Rightarrow Q_F \\
&\text{[Entail-Norm]} \quad P_A \ast P_2 \ast_{sl} (\exists x' \cdot P_1) \Rightarrow Q^1_F \ast Q_1 \ast_{sl} (\exists y' \cdot Q_2) \Rightarrow Q^2_F \\
&\quad \Rightarrow P_A \vdash (\exists x' \cdot \text{req } P_1 \text{ ens } Q_1) \subseteq (\exists y' \cdot \text{req } P_2 \text{ ens } Q_2) \Rightarrow Q^2_F \\
&\text{[Entail-Eff]} \quad P_A \vdash N_1 \subseteq N_2 \Rightarrow Q^1_F \ast_{sl} x=y \land r_1=r_2 \Rightarrow Q^2_F \\
&\quad \Rightarrow P_A \vdash N_1 ; E(x, r_1) \subseteq N_2 ; E(y, r_2) \Rightarrow Q^2_F \\
&\text{[Entail-HO]} \quad P_A \vdash N_1 \subseteq N_2 \Rightarrow Q^1_F \ast_{sl} x'=y' \land r_1=r_2 \Rightarrow Q^2_F \\
&\quad \Rightarrow P_A \vdash N_1 ; g(x', r_1) \subseteq N_2 ; g(y', r_2) \Rightarrow Q^2_F \\
&\text{[Entail-Try-Catch]} \quad P_A \vdash N_1 \subseteq N_2 \Rightarrow Q^1_F \ast \delta_1=\delta_2 \ast Q^2_F \ast \Phi_1 \subseteq \Phi_2 \Rightarrow Q^2_F
\end{align*}
$$

Fig. 24. Selected Entailment Rules for Normalized Staged Flows

Due to the choice of separation logic as a base logic, the entailments between two staged flows are of the form $P_A \vdash \Phi_1 \subseteq \Phi_2 \Rightarrow Q_F$, where $P_A$ is a given assumption (initialized by $\text{emp} \land \text{true}$) and $Q_F$ is the residue (as the result of frame inference), both of which are state formulae. The entailment rules
are shown in Fig. 24. Rules [Entail-LHS-OR] and [Entail-RHS-OR] handle disjunctive antecedents and consequents, respectively. Every flow in the antecedent must be allowed by the consequent, whereas it is acceptable to have additional flows in the consequent that do not correspond to flows in the antecedent. The rest of the rules are for entailments between two disjunction-free staged flows. In particular, the rule [Entail-Flow] demonstrates how the use of normalized specifications “aligns” the antecedent and consequent, allowing entailment proofs to be carried out stage by stage, starting with the heads of both flows. [Entail-Unfold-LHS] allows the use of provided nonrecursive predicate definitions; there is an analogous rule for unfolding on the right. Recursive predicate definitions are handled via lemmas, in the same manner as try-catch formulae. The proving of lemmas is based on the cyclic proof principles [Brotherston 2005], which rewrites the formulae by taking turns applying the unfolding rules and try-catch reduction rules.

Rule [Entail-Norm] handles normal stages, which are pre/post specifications, and this reduces to checking the contra-variance of preconditions and covariance of postconditions. Separation logic proof obligations, i.e., ⊢_SL, are reduced to decidable first-order theory that fits well into the satisfiability modulo theories (SMT) framework, which is standard [Chin et al. 2011; Piskac et al. 2013]. The following rules are for different cases regarding the suffixes of given stages E.

Effect stages and predicate stages whose definitions are unknown are treated similarly, as shown in the rules [Entail-Eff] and [Entail-HO]. When proving the intermediate stages, the symbols, i.e., E or g, used have to match and under the given assumptions P_A and the frame produced by the preceding normal stage Q^f_L, the formal arguments and return variables must be provably equal terms. In the rule [Entail-Try-Catch], try-catch stages must match more or less exactly. Not much is done here as they are best eliminated away by the try-catch reduction; when this is not possible, there is often no better choice than to leave them in specifications.

The entailment checking is terminating because the length of staged flows and the number of disjunctions in Φ are considered finite. The soundness of the entailment checking is defined in Theorem 6.1, making use of a model set relation, defined in Definition 6.1, which abstracts the set of final states that one given ESL specification Φ can accept.

**Definition 6.1 (Model Set Relation).** Given any S, h, SH, and Φ, we say they have the relation of ([✓, S, h] ⊳_{m} \text{SH} \models \Phi), iff SH=\{(C_1, S_1, h_1, R_1) | [✓, S, h] ⊳_{m} [C_1, S_1, h_1, R_1] \models \Phi \} holds.

**Theorem 6.1 (Soundness of Entailment Rules).** If the entailment checking proves that an entailment (P_A ⊢ \Phi_1 \equiv \Phi_2 \models Q^f) is valid, forall S, h, SH_1 and SH_2, if ([✓, S, h] ⊳_{m} \text{SH}_1 \models \Phi_1 \land P_A) and ([✓, S, h] ⊳_{m} \text{SH}_2 \equiv \Phi_2 \land Q^f), then SH_1 \subseteq SH_2 holds.

**Proof.** By induction on the structure of the entailment rule, elaborated in Appendix B.4 [TR 2024].

7 ANOTHER CASE STUDY AND EXPERIMENTAL RESULTS

Apart from proving the soundness of our approach, we prototype an automated verification system (for 5K LoC) on top of OCaml 5, targeting OCaml programs with the effect syntax from Multicore OCaml\(^2\). Here, we demonstrate one more case study and present experimental results based on a suite of benchmark programs. Experiments were done on a MacBook with a 2.6 GHz 6-Core Intel i7 processor. The source code and the evaluation benchmark are openly accessible [Zenodo 2024].

\(^2\)https://github.com/ocaml-multicore/ocaml-multicore
7.1 Case Study: McCarthy’s angelic choice operator

McCarthy’s ambiguous operator amb\(^3\) is an interesting mathematical operator that can rewind into the past whenever it sees trouble and try a different choice. Describing its semantics using multi-shot continuation is much less complex, as shown in Fig. 25. The amb function takes a list of boolean values \(xs\), and its handler iterates the list and resumes the continuation with each boolean element. For simplicity, we used a list of booleans instead of a list of thunks. If \((\text{Failure 500})\) is raised from the continuation, the handler omits the exception and continues the iteration. If any continuation succeeds, it invokes a \(\text{Success}\) effect, which will be caught, re-raised, and caught again; finally, it handles the \(\text{Success}\) effect by returning its carried value. To make the example more challenging, we added a mutable counter to record how many times the iterator had backtracked before reaching the first succeeding element.

\[
\begin{align*}
\text{effect~} \text{Choose} & : \text{bool list} \rightarrow \text{bool} \\
\text{effect~} \text{Success} & : \text{int} \rightarrow \text{unit} \\
\text{effect~} \text{Failure} & : \text{int} \rightarrow \text{int} \\
\text{let} \quad \text{amb} & (xs:\text{bool list}) \text{ counter} : \text{bool} \\
& = \text{let} \quad b = \text{perform} (\text{Choose} \, xs) \text{ in counter} := !\text{counter} +1; \, b \\
\text{let} \quad f \, xs \, \text{counter} = \text{if} \, \text{amb} \, xs \, \text{counter} \text{ then 7 else perform (Failure 500)} \\
\text{let} \quad \text{handle} (xs : \text{bool list}) \text{ counter} : \text{int} \\
& = \text{match} (f \, xs \, \text{counter}) \text{ with} \\
& \quad | x \rightarrow x \\
& \quad | \text{effect (Choose} \, xs) \, k \rightarrow \\
& \quad \text{match} \text{List.iter (fun} \, \text{ele} \rightarrow \\
& \quad \text{match} \, \text{let} \quad \text{seven} = \text{resume} \, k \, \text{ele} \text{ in perform (Success seven) with} \\
& \quad \text{| effect (Success} \, x) \, k \rightarrow \text{perform (Success} \, x) \\
& \quad \text{| effect (Failure} \, _) \, k \rightarrow () \text{ (* Omitting Failure 500 *)} \\
& \quad \text{| _} \rightarrow () \\
& \text{)} \, xs; \text{ (* iterate the lambda elements from xs *)} \\
& \text{perform (Failure} \, 404) \\
& \text{with} \quad | x \rightarrow x \quad | \text{effect (Success} \, r) \, k \rightarrow r \text{ (* Leaking Failure 404 *)}
\end{align*}
\]

Fig. 25. McCarthy’s Locally Angelic Choice Operator

This example is non-trivial as it involves nested handlers with higher-order functions; heap-manipulating behaviors in the continuation; performing effects while handling effects; encoding exceptions using effects; and last but not least, reasoning is also required on the list data structure.

We present the specifications for handle and the key predicate definitions in Fig. 26. Recursively defined predicate containRetTrue takes a list \(xs\), uses a Boolean variable \(r\) to denote if there exists an element from the list \(xs\) which equals to true, and uses an integer \(p\) to denote the position of such an element. In case there isn’t such an element, \(p\) equals the length of the list. The specification for handle indicates that if there exists one element in a given list \(xs\), that equals to true, then it returns 7, and the counter is increased by the position of the value, \(p\); otherwise, it carries an unhandled effects (Failure 404) as the final result. From the specification, we can see that the (Failure

\(^3\)https://okmij.org/ftp/ML/ML.html#amb
containRetTrue(xs, p, r) = ens[r] xs=[] ∧ p=0 ∧ r=false
                                 ∨ ∃h, t · ens[r] xs=h::t ∧ h=true ∧ p=1 ∧ r=true
                                 ∨ ∃h, t, p’ · ens[r] xs=h::t ∧ h=false ∧ p=p’+1 ∧ containRetTrue(t, p’, r)

List.iter(f, xs, r) = ens[r] xs=[] ∧ r=() ∨ ∃h, t · ens xs=h::t; f(h, ()) ; List.iter(f, t, r)

amb(xs, counter, r) = ∃b · Choose(xs, b) ; ∃z · req counter→z ens[r] counter→z+1 ∧ r=b

f(xs, counter, r) = ∃b · amb(xs, counter, b) ; (ens[r] b=true ∧ r=7 ∨ ens b=false ; Failure(500, r))

handle(xs, counter, r) = ∃z, p, b · req counter→z ∧ containRetTrue(xs, p, b) ;
                         (ens[r] counter→z+p ∧ b=true ∧ r=7 ∨ ens counter→z+p ∧ b=false ; Failure(404, r))

Fig. 26. Specification for the handle Function and Deployed Predicate definitions

500) effects possibly performed by f – indicate the failure of individual attempts – will be omitted by the handler at line 17, whereas (Failure 404) effects performed in the handler at line 20 may escape the handle function, to indicate that there is no element in xs which equals to true.

7.2 Experimental Results

The benchmark programs in Table 1 are based on the examples from various sources. More specifically, program 1 is taken and revised from a Memory Cell with Exchange example in the prior work [de Vilhena and Pottier 2021], to further model different operations with a state monad, including read, write, exchange values, and applications of their combinations. Programs 3 and 7 are originally from the multicont library, which provides practical examples for multi-shot continuations. Program 5 revises program 3 by changing the handler to be shallow. Programs 4 and 6 demonstrate the usages of lemmas for left recursive functions in both deep and shallow handlers. Program 2 is newly created in this work for feature diversity.

</table>

In Table 1, columns LoC and LoS record the lines of code and lines of specification, respectively. The column Total sums up the time for forward reasoning and entailment checking. The column AskZ3 records the time consumed by the Z3 solver during the whole verification process. Times are measured in seconds. Although forward reasoning and entailment checking are mostly automated, we show that the verification is non-trivial by labeling the programs with features: Ind indicates

whether the proof is inductive, MultiS means if the program uses multi-shot handlers, ImpureC indicates if there exist heap-manipulation operations in the continuations. Lastly, HO indicates if the program is higher-order, i.e., function inputs or outputs are of function type.

As shown, for 461 lines of code in total, our verification system intakes 129 lines of specifications, with an average LoS/LoC ratio of 28%. For the time consumption, majority of the time is consumed by the Z3 solving – taking up 68.8% (23.32/33.88) of the total verification time. To the best of the authors’ knowledge, this work is the first that provides verification solutions for the given benchmark and supports automated proofs, demonstrating the feasibility of ESL. Due to space limitation, we demonstrate the verification for programs 1, 2, 4, 5, and 6 in Appendix C [TR 2024].

8 RELATED WORK

In this section, we discuss related works on the reasoning of algebraic effects and delimited control, applications for multishot continuations, and other structured specifications.

Reasoning about algebraic effects and delimited control. For decades, monads [Moggi 1989; Wadler 1990] have dominated the scene of functional programming with effects. The recent popularization of algebraic effects and handlers [Bauer and Pretnar 2015; Plotkin and Pretnar 2009] promises to change the landscape. To support resumption, an effect handler has access to the continuation at the point of effect invocation. Thus, algebraic effects and handlers provide a form of delimited control operators, which have long been used to encode effects [Danvy 2006]. In monads, the effectful behavior is defined in bind and return, statically determining the behavior inside the do block. Whereas the behaviors of performing algebraic effects are determined dynamically by the encompassing handlers, which gives greater flexibility in the composition of effectful code, but it also requires additional reasoning to regulate the composed behaviors.

Many prior works study the semantics of effects and effect handlers in a pure setting. For instance, Plotkin and Pretnar [2008] propose a logic to reason about the equality of computations in a calculus with effects but no handlers. They later introduce effect handlers as an internal way of giving meaning to effects [Plotkin and Pretnar 2013] and discuss a notion of correctness whereby a handler is correct if it satisfies an intended equational theory. In addition, there is also a bulk of work on temporal verification for algebraic effects. For example, Gordon [2020] are concerned with infinite-state higher-order programs with control operators using type and effect systems, and it defines a framework for sequential effects with tagged control operators akin to abort and call/cc, capturing temporal safety properties. Song et al. [2022] propose a trace-based logic for practical automated temporal verification of effect handlers. Closely related are verification works for delimited control operators and properties beyond the safety and liveness of individual programs. Kiselyov et al. [2021] recover equational reasoning in the presence of effect handlers. Sekiyama and Unno [2023] present a type-and-effect system for shift/reset [Materzok and Biernacki 2011] which reasons about the traces that continuations generate, supporting liveness reasoning. Afterward, a follow-up work [Kawamata et al. 2024] proposes a refinement type system for languages with algebraic effects and handlers. These earlier works typically avoid heap-manipulating behaviors.

Till [Delbianco and Nanevski 2013] propose HTTcc, a separation logic for calculus with dynamically allocated mutable state and an algebraic variant of call/cc and throw. It uses a "large footprint" assertions, and does not have a frame rule, which means that it imposes reasoning about the entire heap, different from [de Vilhena and Pottier 2021] and our approach, which reasons about a heap fragment and exploits a frame rule to argue that the rest of the heap is preserved.

\[^{5}\text{For better precision, some pre-analysis and encoding are carefully designed, which query Z3 additionally to incorporate the multiplication operator in program 2 and the power operator used in programs 3-4.}\]
The current state-of-the-art for verifying imperative behaviors in algebraic effects and handles is [de Vilhena and Pottier 2021]. It specifies program behaviors using separation logic and client-handler interactions in the form of protocols, which globally define the effects that clients may perform and the replies they may receive from handlers. A similar protocol-based solution is used in Cameleer [Soares and Pereira 2023], which encodes effects as WhyML exceptions and uses defunctionalization to represent higher-order continuations. However, these solutions are restricted to one-shot continuations because those protocols are incapable of accessing and composing the continuations explicitly. Subsequently, de Vilhena [2022] extends de Vilhena and Pottier [2021] to multi-shot resumption, restrictively allowing only persistent assertions in the continuations of effects. The extension, however, still precludes multi-shot impure continuations, e.g., the examples in Sec. 3.1 and Fig. 5. This key limitation motivates our work, and we propose ESL to fill this gap by naturally supporting unrestricted handlers with heap-based continuations. As a final note, protocol-based solution uses global assumptions on handlers to provide explicit (or early) interpretation for each of the algebraic effects. In theory, this explicit approach could help simplify the reasoning needed for algebraic effects. However, in reality, it also leads to restrictions on the types of continuations that can be supported for multi-shot handlers, and moreover loses some flow-sensitivity that is inherent in try-catch handling of effects with continuations. In contrast to protocol-based approach, our solution models try-catch handlers separately from effect invocations, and delays the interpretation of the algebraic effects until try-catch handlers are defined and where the scope of the continuation(s) would also become known. It would be interesting to explore how the benefits from both these approaches could be combined.

**Applications of multishot continuations.** Most effects may be implemented using one-shot continuations [Bruggeman et al. 1996]. Two exceptions are i) to implement a Unix-style asynchronous fork primitive [Leijen 2017]; and ii) nondeterminism. The latter is useful in backtracking, probabilistic programming [Nguyen et al. 2022]⁶, and model checking⁷; as multi-shot handlers naturally express the branching points in search. While backtracking may be expressed by lifting client programs to asymmetric coroutines [de Moura and Jerusalimschy 2009] [closely related to one-shot continuations [Kawahara and Kameyama 2020]], this approach is not modular and does not allow for the creation of abstractions, as effects do. Moreover, nondeterminism may be implemented by throwing exceptions and saving enough state to replay to branching points [Koppel et al. 2018], but this approach incurs runtime overhead from repeated computations, and it assumes the absence of side effects. In contrast, the main advantages of multi-shot continuations are that they simplify the implementation of complex algorithms and generally perform better by incurring more memory overheads instead.

**Verifying Higher-Order Imperative Programs.** An early approach for reasoning about higher-order imperative programs in pre/post Hoare logic was proposed by Honda et al. [Yoshida et al. 2007]. Our work drew early inspiration from this line of work, and have now considerably extended it to take into account algebraic effects, try-catch handlers and continuations. Our current solution is also built on top of the staged specification mechanism [Foo et al. 2024] that we have recently proposed to support formal reasoning of imperative higher-order programs. With this new work, we have now extended it to handle algebraic effects, showed how delimited continuations can be captured via staged flows and modelled try-catch logic reduction in a general but precise manner.

⁷https://github.com/ocaml-multicore/dscheck
9 CONCLUSION

This work is mainly motivated by how to modularly specify and verify heap-manipulating programs with multi-shot effect handlers. We present an Effectful Specification Logic to write compact and generic specifications for target programs. Our contributions are manifold: we define the forward reasoning rules for a core language, we devise a set of reduction rules to calculate the heap-manipulating behaviors for effect handlers, where zero-/one-/multi-shot continuations coexist. We prototype and automate the proposal, present experimental results, and demonstrate nontrivial and practical case studies to show feasibility. To the best of the authors’ knowledge, this work is the first that lays the foundation for a practical verification framework that is capable of modeling arbitrary imperative higher-order programs with algebraic effects and unrestricted handlers.

A MORE RECURSION WITH LEMMA EXAMPLES

In this section, we present the lemmas for proving the left recursive toss function in the context of the deep handler and shallow handlers, in Sec. A.1 and Sec. A.2, respectively. Before that, we define the implementation and specification for tossNLeft in Fig. 27.

```plaintext
let n ->

(* tossN(n, res) = r0 .. n .. Flip(r0); res = r0 ∨
  r1 .. n .. Flip(r1) .. res = r1 ∧ r2 *)

let tossNLeft n

(* tossNLeft(n, res) = r0 .. n .. Flip(r0); res = r0 ∨
  r1 .. n .. Flip(n-1, r1); res = (r1 ∧ r2 *)

= match n with
  | 1 -> perform Flip
  | n -> let r1 = tossNLeft (n - 1) in
  let r2 = perform Flip in r1 && r2
```

_Fig. 27._ Flipping a coin n times (left recursion)

A.1 Deep handler with left recursion

Fig. 28 presents the lemma for handling tossNLeft in the same deep handler (defined in Fig. 7). The proof for the lemma is in Fig. 29. Finally, we derive the actual behavior of the handler by instantiating the lemma, i.e., ∃r · Φinv(1, m, true, r); and generate the entailment for proving all_results's specification in Fig. 30.

Φinv(n, m, acc, r) = ∃w · ¬head w · helper(m, acc, r) catch H₀ = ∃r ∈ Φinv(n, m, acc, r)

_Fig. 28._ A try-catch lemma for the left recursion tossNLeft in a deep handler

```plaintext
try ∃res · tossNLeft(n, res) # ∃r’ · helper(m, acc, res, r’) catch H₀  (When n=1)

~ try ∃res · ens n=1; Flip(res) # ∃r’ · helper(m, acc, res, r’) catch H₀ [R-Eff-Handle]
~ ens n=1; w1 .. req counter=w1 ens counter=w1+1; r1’ · helper(m, acc, true, r1’);
  w2 .. req counter=w2 ens counter=w2+1; r2’ · helper(m, acc, false, r2’); ∃r · ens[r] r=r1’+r2’
~ ∃r, w · req counter=w1 ens[r] counter=w1+2^m-2 ∧ n=1 ∧ (acc ∨ acc ∧ r=0)
~ ∃r, w · req counter=w1 ens[r] counter=w1+2^m-2 ∧ n=1 ∧ (acc ∨ acc ∧ r=0)
```

_Fig. 29._ Detailed proof for the lemma in Fig. 28, for the left recursion tossNLeft in a deep handler

Proc. ACM Program. Lang., Vol. 8, No. ICFP, Article 267. Publication date: August 2024.
A.2 Shallow handler with left/right recursion

The specification for the all_results function (cf. Fig. 7) with a shallow handler is defined in Fig. 31.

\[ \text{all_results_shallow}(\text{counter}, n, r) = \exists w \cdot \text{req} \text{counter} \rightarrow w \ens \text{counter} \rightarrow w+2 \land n=1 \land r=1 \lor \exists w_1, r_1 \cdot \text{req} \text{counter} \rightarrow w_1 \ens \text{counter} \rightarrow w_1+1; \text{tossN}(n-1, r_1); \ens[r] r=r_1 \]  

When tossN is the right recursion, all_results_shallow can be proved by reducing the shallow handler without lemmas. Nevertheless, here we show how to prove the specification when toss is left recursion. Fig. 32 presents the lemmas for handling tossNLeft in the same handler (defined in Fig. 7), but shallow. The proof for the lemma1 and lemma2 are in Fig. 33 and Fig. 34 respectively.

Fig. 31. Specification for all_result when it’s shallow, assuming the final normal return clause is unchanged.

\begin{align*}
\Phi_{\text{inv}}(n, m, \text{acc}, r) &= \exists w_1, r_1 \cdot \text{req} \text{counter} \rightarrow w_1 \ens \text{counter} \rightarrow w_1+1; \text{helper}(n+1+m, \text{acc}, r_1); \\
&\quad \exists w_2, r_2 \cdot \text{req} \text{counter} \rightarrow w_2 \ens \text{counter} \rightarrow w_2+1; \text{helper}(n+1+m, \text{false}, r_2); \ens[r] r=r_1 \\
\text{helper}(m, \text{acc}, r') &= \ens m=0; \ens[r'] (\text{acc} \land r' = 1 \lor \neg \text{acc} \land r' = 0) \lor \\
&\ens m>0; \exists r_1 \cdot \text{Flip}(r_1); \exists r_2 \cdot \text{helper}(m-1, \text{acc}, r_1, r_2); \ens[r] r=r_2 \\
\text{tossNAux}(m, \text{acc}, r) &= \exists r_1 \cdot \text{tossN}(m, r_1); \ens[r] (\text{acc} \land r_1) \land r=1 \lor \neg (\text{acc} \land r_1) \land r=0
\end{align*}

Lemma1: \( \exists r \cdot \ens m>0; \text{helper}(m, \text{acc}, r) \sqsubseteq \exists r \cdot \text{tossNAux}(m, \text{acc}, r) \)

Lemma2: try \( \exists res \cdot \text{tossNLeft}(n, res) \# \exists r' \cdot \text{helper}(m, \text{acc}, res, r') \text{ catch } \mathcal{H}_{\Phi} = \exists r \sqsubseteq \Phi_{\text{inv}}(n, m, \text{acc}, r) \)

Fig. 32. The try-catch lemma for the left recursion tossNLeft in a shallow handler.

\begin{align*}
\exists r \cdot \ens m=1; \text{helper}(m, \text{acc}, r) &\quad (\text{When } m=1) \\
\Rightarrow \exists r, r_1 \cdot \text{Flip}(r_1); \exists r_2 \cdot \text{helper}(0, \text{acc}, r_1, r_2); \ens[r] r=r_2 \\
\Rightarrow \exists r, r_1 \cdot \text{Flip}(r_1); \ens[r] (\text{acc} \land r_1) \land r=1 \lor \neg (\text{acc} \land r_1) \land r=0 \sqsubseteq \exists r \cdot \text{tossNAux}(1, \text{acc}, r)
\end{align*}

Fig. 35. Try-catch reduction when handling tossNLeft in a shallow handler (base case)

We prove the specification for all\_results\_shallow for the base case (n=1) in Fig. 35. Finally we derive the actual behavior of the handler by instantiating the verified lemma, i.e., \exists r · \Phi \inv(n, 0, true, r), for the inductive case (n=1) in Fig. 36. In particular, it makes use of the lemma1, which builds the connection between a left recursion and a right recursion.

B SOUNDNESS

B.1 Soundness of the Try-Catch Reduction

**Theorem 5.1 (Soundness of Reduction).** Given any try-catch reduction, \( \text{try}[^{\delta}(\Phi)] \text{catch} \mathcal{H}_\Phi \leadsto \Phi' \); for all \( S, h, C_1, S_1, h_1, \) and \( R_1 \), if \( \exists \ LHS \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\Phi)] \text{catch} \mathcal{H}_\Phi \), then \( \exists \ RHS \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \Phi' \) holds.

**Proof.** By induction on the structure of the reduction rule.

1. For \( \lbrack \mathcal{R-\text{Normal}} \rbrack \), let \( \text{LHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \Phi \models \Phi' \), and \( \exists \) \( \text{RHS} \text{ by semantics}: \lbrack C_1 = C_2, S_1 = S_2, h_1 = h_2 \) and \( \exists \ r_1 = r_2 \).

2. For \( \lbrack \mathcal{R-\text{Skip}} \rbrack \), let \( \text{LHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \E ; \theta \text{ catch} \mathcal{H}_\Phi \), and given \( \exists \) \( \text{RHS} \text{ by semantics}: \exists \ E \models \text{try}[^{\delta}(\theta)] \text{catch} \mathcal{H}_\Phi \), and given \( \exists \ E \models \text{try}[^{\delta}(\theta)] \text{catch} \mathcal{H}_\Phi \).

3. For \( \lbrack \mathcal{R-\text{Unfold}} \rbrack \), let \( \exists \) \( \text{LHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\mathcal{N} ; \Phi_f[v/x^*, r'/r]) \text{ catch} \mathcal{H}_\Phi \), and given \( \exists \) \( \text{RHS} \text{ by semantics}: \exists \mathcal{N} ; \Phi_f[v/x^*, r'/r] \models \text{try}[^{\delta}(\theta)] \text{catch} \mathcal{H}_\Phi \).

4. For \( \text{R-Shallow} \), let \( \exists \) \( \text{LHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\mathcal{E} ; \theta)] \text{catch} \mathcal{H}_\Phi \), and given \( \exists \) \( \text{RHS} \text{ by semantics}: \exists \mathcal{E} \models \text{try}[^{\delta}(\mathcal{E} \# \Phi)] \text{catch} \mathcal{H}_\Phi \).

5. For \( \text{R-Deep} \), let \( \exists \) \( \text{LHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\mathcal{E} \# \Phi)] \text{catch} \mathcal{H}_\Phi \), and given \( \exists \) \( \text{RHS} \text{ by semantics}: \exists \mathcal{E} \models \text{try}[^{\delta}(\mathcal{E} \# \Phi)] \text{catch} \mathcal{H}_\Phi \).

6. For \( \text{R-Eff-Handle} \), let \( \exists \) \( \text{LHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\mathcal{E} \# \Phi)] \text{catch} \mathcal{H}_\Phi \), and given \( \exists \) \( \text{RHS} \text{ by semantics}: \exists \mathcal{E} \models \text{try}[^{\delta}(\mathcal{E} \# \Phi)] \text{catch} \mathcal{H}_\Phi \).

7. For \( \text{R-Lemma-App} \), let \( \exists \) \( \text{LHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\mathcal{E} \# \Phi)] \text{catch} \mathcal{H}_\Phi \), and given \( \exists \) \( \text{RHS} \text{ by semantics}: \exists \mathcal{E} \models \text{try}[^{\delta}(\mathcal{E} \# \Phi)] \text{catch} \mathcal{H}_\Phi \).

8. For \( \text{R-Disj} \), let \( \exists \) \( \text{LHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\Phi)] \text{catch} \mathcal{H}_\Phi \), and given \( \exists \) \( \text{RHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\Phi)] \text{catch} \mathcal{H}_\Phi \). Assuming that \( \exists \) \( \text{LHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\Phi)] \text{catch} \mathcal{H}_\Phi \), and given \( \exists \) \( \text{RHS} \text{ by semantics}: \lbrack \exists, S, h \rbrack \leadsto_m \lbrack C_1, S_1, h_1, R_1 \rbrack \models \text{try}[^{\delta}(\Phi)] \text{catch} \mathcal{H}_\Phi \).
All the reduction rules are sound, thus the try-catch reduction process is sound.

B.2 Soundness of the Normalization Rules

Theorem 5.2 (Soundness of Normalization). Given any normalization rule, if it concludes that
\((\varphi \rightarrow \Phi); \text{forall } S_0, h_0, C_1, S_1, h_1, \text{ and } R_1, \text{ if } [\checkmark, S_0, h_0] \sim_m [C_1, S_1, h_1, R_1] \models \varphi, \) then \([\checkmark, S_0, h_0] \sim_m [C_1, S_1, h_1, R_1] \models \Phi \text{ holds.}\)

Proof. By induction on the structure of the normalization rule.

(1) For the rule \([N\text{-Norm-Dis}], \text{let LHS=} N; (\Phi_1 \lor \Phi_2) \text{ and RHS=} \Phi_1 \lor \Phi_2', \text{ let us assume}
\[[\checkmark, S_0, h_0] \sim_m [C, S, h, R] \models N, ] [C, S, h] \sim_m [C_2, S_2, h_2, R_2] \models \Phi_1, ] [C, S, h] \sim_m [C_3, S_3, h_3, R_3] \models \Phi_2.
(\text{LHS}) \text{By semantics, if given } [\checkmark, S_0, h_0] \sim_m [C_1, S_1, h_1, R_1] \models N; (\Phi_1 \lor \Phi_2') \text{ then}
C_1=(C_2 \land C_3) \text{ and } (S_1, h_1, R_1) \in \{(S_2, h_2, R_2), (S_3, h_3, R_3)\},
\text{also by the promises: } [\checkmark, S_0, h_0] \sim_m [C_2, S_2, h_2, R_2] \models \Phi_1', \text{ and } [\checkmark, S_0, h_0] \sim_m [C_3, S_3, h_3, R_3] \models \Phi_2';
\text{therefore for the RHS, we have } [\checkmark, S_0, h_0] \sim_m [C_1, S_1, h_1, R_1] \models \Phi_1 \lor \Phi_2'.

(2) For the rule \([N\text{-Norm-Flow}], \text{let LHS=} N; \theta \text{ and RHS=} N''; \theta', \text{ let us assume}
\[[\checkmark, S_0, h_0] \sim_m [C, S, h, R] \models N, ] [C, S, h] \sim_m [C_2, S_2, h_2, R_2] \models N''.
(\text{LHS}) \text{By semantics, if given } [\checkmark, S_0, h_0] \sim_m [C_1, S_1, h_1, R_1] \models N; N'; \theta'.
\text{also by the promises, we have: } [\checkmark, S_0, h_0] \sim_m [C_2, S_2, h_2, R_2] \models N'',
\text{therefore for the RHS, we have } [\checkmark, S_0, h_0] \sim_m [C_1, S_1, h_1, R_1] \models N''; \theta'.

(3) For the rule \([N\text{-Norm-Norm}], \text{let LHS=} N; N', \text{ and RHS=} N''', \text{ let us assume}
\[[\checkmark, S_0, h_0] \sim_m [C_2, S_2, h_2, R_2] \models \exists x, y \cdot \text{req } P,
[C_2, S_2, h_2] \sim_m [C_3, S_3, h_3, R_3] \models \text{ens } Q,
[C_3, S_3, h_3] \sim_m [C_4, S_4, h_4, R_4] \models \text{req } P',
[C_4, S_4, h_4] \sim_m [C_5, S_5, h_5, R_5] \models \text{ens } Q'.
(\text{LHS}) \text{By semantics, if given } [\checkmark, S_0, h_0] \sim_m [C_1, S_1, h_1, R_1] \models N; N'.
\text{also by the promises, we have: } [C_2, S_2, h_2] \sim_m [C_4, S_4, h_4, R_4] \models \text{req } PA \text{ ens } QF, \text{ therefore,
}[\checkmark, S_0, h_0] \sim_m [C_1, S_1, h_1, R_1] \models \exists x, y \cdot \text{req } P; \text{ req } PA; \text{ens } QF; \text{ens } Q'.
\text{therefore for the RHS, we have } [\checkmark, S_0, h_0] \sim_m [C_1, S_1, h_1, R_1] \models N'''.

All the normalization rules are sound, thus the normalization process is sound.

B.3 Soundness of Forward Rules

Theorem 5.3 (Soundness of Forward Rules). If the forward reasoning concludes that a given triple
\(\{\varphi\} \models \{\Phi\}\) is valid, forall \(S_0\) and \(h_0\), if \([\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}(\_)] \models N,\) and
let \(SH=\{(S_1, h_1, R_1) \mid [\checkmark, S_0, h_0] \sim_m [\checkmark, S_1, h_1, R_1] \models \Phi\},\) and \(SH\neq\emptyset,\) then \([S, h, e] \rightarrow [S_2, h_2, R_2] \land R_2\neq\text{Err} \land \exists(S_3, h_3, R_3) \in SH \cdot ([\checkmark, S_0, h_0] \sim_m [\checkmark, S_3, h_3, R_3] \models \Phi \land S_3\geq S_2, h_3=h_2, R_2\in R_3).

Proof. By induction on the derivation of \([S, h, e] \rightarrow [S_2, h_2, R_2].\)

- \(e\) is a variable \(x.\)

\[ [S, h, x] \rightarrow [S_2, h_2, R_2] \]
where \((S_2, h_2, R_2) = (S, h, \text{Norm}(S(x))).\)
From $\vdash \{N\} x \{\Phi\}$, using the rule $[FV\text{-}Var\text{-}Const]$,

\[ N = \text{req } P \text{ ens } Q[\_]. \]

\[ \Phi = \exists r \cdot \text{req } P \text{ ens}[r] Q \land r=x. \]

Given $[\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}(\_)] \models N$, the semantics of $\Phi$ is:

\[ [\checkmark, S_0, h_0] \sim_m [\checkmark, S_3, h_3, R_3] \models \Phi \]

where $(S_3, h_3, R_3) = (S+[r:=v], h, \text{Norm}(r))$ for some $v$.

We know also that $S+[r:=v], h \models r=x$.

Thus $R_2 = S(r) = v = S(x) = R_3 \neq \text{Err}$, $S_3 = S+[r:=v] \supset S_2$, and $h_3 = h_2$.

- $e$ is a constant $c$.
  - This case is the same as the case for variables, with the exception that the result is $c$ instead of $S(x)$.

- $e$ is of the form $\text{ref}(x)$.

$e$ evaluates as follows:

\[ [S, h, \text{ref}(x)] \longrightarrow [S_2, h_2, R_2] \]

where $(S_2, h_2, R_2) = (S, h[l:=S(x)], \text{Norm}(l))$.

From $\vdash \{N\} \text{ref}(x) \{\Phi\}$, using the rule $[FV\text{-}Ref]$,

\[ N = \text{req } P \text{ ens } Q. \]

\[ \Phi = \exists y \cdot \text{req } P \text{ ens}[y] Q \land y \mapsto x. \]

Given $[\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}(\_)] \models N$, the semantics of $\Phi$ is:

\[ [\checkmark, S_0, h_0] \sim_m [\checkmark, S_3, h_3, R_3] \models \Phi \]

where $(S_3, h_3, R_3) = (S+[y:=v], h[S(y)]:=S(x)], \text{Norm}(y))$ for some $v$.

We know also that $S_3, h_3 \models y \mapsto x$.

Choosing $t$ for $v$, $R_2 = l = v = S(y) = R_3 \neq \text{Err}$, $S_3 \supset S_2$, and $h_3 = h_2$.

- $e$ is of the form $!x$.

$e$ evaluates as follows:

\[ [S, h, !x] \longrightarrow [S_2, h_2, R_2] \]

where $(S_2, h_2, R_2) = (S, h, \text{Norm}(h(S(x))))$.

From $\vdash \{N\} !x \{\Phi\}$, using the rule $[FV\text{-}Read]$,

\[ N = \text{req } P \text{ ens } Q. \]

\[ \Phi = \exists z \cdot \text{req } P \ast P_A \text{ ens}[z] Q_F \land x \mapsto z. \]

There are two cases.

1. $x \mapsto z$ is in $Q$. Then $P_A = \text{emp}, Q_F = (x \mapsto z) \ast \ast Q$.

\[ \Phi = \exists z \cdot \text{req } P \text{ ens}[z] ((x \mapsto z) \ast \ast Q) \land x \mapsto z \]

\[ = \exists z \cdot \text{req } P \text{ ens}[z] Q \]

Given $[\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}(\_)] \models N$, the semantics of $\Phi$ is:

\[ [\checkmark, S_0, h_0] \sim_m [\checkmark, S_3, h_3, R_3] \models \Phi \]

where $(S_3, h_3, R_3) = (S, h, \text{Norm}(z))$ for some $v$.

Intuitively, we temporarily remove the assertion $x \mapsto z$ to access its value.
(2) $x \mapsto z$ is not in $Q$. Then $P_A = x \mapsto z, Q_F = Q$.

$\Phi = \exists z \cdot \text{req} \ (P \ast x \mapsto z) \ \text{ens}[z] \ (Q \ast x \mapsto z)$.

Intuitively, we propagate $x \mapsto z$ to the precondition. It must be that $S_0, h_0 \vdash x \mapsto z$ despite it not being mentioned by $N$.

Given $[\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}(\_)] \models N$, the semantics of $\Phi$ is:

$[\checkmark, S_0, h_0] \sim_m [\checkmark, S_3, h_3, R_3] \models \Phi$

where $(S_3, h_3, R_3) = (S, h, \text{Norm}(z))$ for some $v$.

We know also that $S_3, h_3 \models x \mapsto z$.

Either way, $h_2 = h_3, S_3 \supseteq S_2$, and the result is the variable $z$, whose value will be $S(z) = h(S(x))$.

• $e$ is of the form $x := y$.

The proof of this case is almost the same as that for $!x$, also requiring that $Q$ contains a heap assertion about $x$, strengthening the precondition with it if not.

The only changes to the proof are that the location in the heap has value $S(y)$ after, and the result is the unit value.

e evaluates as follows:

$[S, h, x := y] \rightarrow [S_2, h_2, R_2]$

where $(S_2, h_2, R_2) = (S, h[S(x) := S(y)], \text{Norm}(()))$.

From $\models \{N\} x := y \ {\Phi}$, using the rule $[\text{FV-Write}]$,

$N = \text{req} \ P \ \text{ens} \ Q$.

$\Phi = \exists r \cdot \text{req} \ P \ast P_A \ \text{ens}[r] \ Q_F \ast x \mapsto y \land r = ()$.

There are two cases.

(1) $x \mapsto _\_ \ast$ is in $Q$. Then $P_A = \text{emp}, Q_F = (x \mapsto _\_ \ast) \ast Q$.

$\Phi = \exists r \cdot \text{req} \ P \ \text{ens}[r] \ ((x \mapsto _\_) \ast Q) \ast x \mapsto y \land r = ()$

Given $[\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}(\_)] \models N$, the semantics of $\Phi$ is:

$[\checkmark, S_0, h_0] \sim_m [\checkmark, S_3, h_3, R_3] \models \Phi$

where $(S_3, h_3, R_3) = (S, h[S(x) := S(y)], \text{Norm}(()))$ for some $v$.

(2) $x \mapsto _\_ \ast$ is not in $Q$. Then $P_A = x \mapsto _\_, Q_F = Q$.

$\Phi = \exists z \cdot \text{req} \ (P \ast x \mapsto _) \ \text{ens}[z] \ (Q \ast x \mapsto _)$.  

It must be that $S_0, h_0 \vdash x \mapsto _\_ \ast$ despite it not being mentioned by $N$.

Given $[\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}(\_)] \models N$, the semantics of $\Phi$ is:

$[\checkmark, S_0, h_0] \sim_m [\checkmark, S_3, h_3, R_3] \models \Phi$

where $(S_3, h_3, R_3) = (S, h[S(x) := S(y)], \text{Norm}(z))$ for some $v$.

Either way, $h_2 = h_3, S_3 \supseteq S_2$, and the result is the unit value.
• $e$ is of the form assert $\sigma \land \pi$.

$e$ evaluates as follows:
$[S, h, assert \sigma \land \pi] \rightarrow [S_2, h_2, R_2]$
where $(S_2, h_2, R_2) = (S, h, \text{Norm}())$.

From $\vdash \{N\}$ assert $\sigma \land \pi \{\Phi\}$, using the rule [FV-Assert],
$\mathcal{N} = \exists z \cdot \text{req } \Phi \ens[z] Q_f \times x \mapsto z$.

There are two cases.
(1) $Q$ implies $\sigma \land \pi$. Then $P_A = \text{emp}$.
$\Phi = \exists r \cdot \text{req } \ens[r] Q \land r=()$.

Given $[\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}()] = \mathcal{N}$, the semantics of $\Phi$ is:
$[\checkmark, S_0, h_0] \sim_m [\checkmark, S_3, h_3, R_3] \vdash \Phi$
where $(S_3, h_3, R_3) = (S, h, \text{Norm}())$ for some $v$.

(2) $Q$ does not imply $\sigma \land \pi$. Then $P_A = \sigma \land \pi$.
$\Phi = \exists r \cdot \text{req } (P \land \sigma \land \pi) \ens[r] (Q \land \sigma \land \pi \land r=())$.

It must be that $S_0, h_0 \models \sigma \land \pi$ despite it not being mentioned by $\mathcal{N}$.

Given $[\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}()] = \mathcal{N}$, the semantics of $\Phi$ is:
$[\checkmark, S_0, h_0] \sim_m [\checkmark, S_3, h_3, R_3] \vdash \Phi$
where $(S_3, h_3, R_3) = (S, h, \text{Norm}())$ for some $v$.

Either way, $h_2 = h_3, S_3 \supseteq S_2$ (since the stage is unchanged), and the result is the unit value.

• $e$ is of the form let $x = e_1$ in $e_2$.

$e$ evaluates as follows:
$[S, h, let \ x = \ e_1 \ in \ e_2] \rightarrow [S, h_2, R_2]$
iff $[S, h, e_1] \rightarrow [S_2', h_2', R_2']$ and $[S+\{x:=e_2\}, h_2', e_2] \rightarrow [S_2, h_2, R_2]$

From $\vdash \{N\}$ let $x = e_1$ in $e_2 \{\Phi\}$, using the rule [FV-Let], we have $\Phi' = \exists x; \Phi$ where $\vdash \{N\} e_1 \{E^*; N_1[r]\}$ and $\vdash \{N_1 \land x=r\} e_2 \{\Phi\}$.

From the promise, we have $[\checkmark, S, h] \sim_m [\checkmark, S_2', h_2', R_2'] \vdash E^*; N_1[r]$ and $[\checkmark, S_2'+\{x:=r\}, h_2', R_2] \sim_m [\checkmark, S_2, h_2, R_2] \vdash \Phi$;
therefore the actual execution trace from $[\checkmark, S_0, h_0]$ to $[\checkmark, S_2, h_2, R_2]$ has a witness in the model of the specifications $\Phi'$, therefore the rule is sound.

• $e$ is of the form if $x$ then $e_1$ else $e_2$.

$e$ evaluates as follows:
$[S, h, if \ x \ then \ e_1 \ else \ e_2] \rightarrow [S_2, h_2, R_2]$
if $S(x) = \text{true}$ and $[S, h, e_1] \rightarrow [S_2, h_2, R_2]$.
We focus on the case where $S(x) = \text{true}$, as the false case is symmetric and very similar.

From $\vdash \{N\}$ if true then $e_1$ else $e_2 \{\Phi\}$, using the rule [FV-If-Else],
$\Phi = \Phi_1$.

Given $[\checkmark, S_0, h_0] \sim_m [\checkmark, S, h, \text{Norm}()] = \mathcal{N}$,
\[ [\checkmark, S_0, h_0] \leadsto_m [\checkmark, S, h, \text{Norm}(\_)] \models N \land x \text{ since } S(x) = \text{true}. \]

From the induction hypothesis,
\[ [\checkmark, S_0, h_0] \leadsto_m [\checkmark, S_2, h_2, R_2] \models \Phi \]

Thus \( S_3 \supseteq S_2, h_3 = h_2, \) and \( R_2 = R_3 \neq \text{Err}. \)

- \( e \) is of the form \( f(x). \)

\( e \) evaluates as follows:
\[ [S, h, f(x)] \longrightarrow [S_2, h_2, R_2] \]
if \( S(f) = (\lambda y \rightarrow e_f, S_f) \) and
\[ [S+h, h, e[x/y]] \longrightarrow [S_2, h_2, R_2] \]

We focus on the case where \( f \) is known, since \( e \) can execute.

From \( \vdash \{ N \} f(x) \{ \Phi \}, \) using the rule \([FV-Pred], \)
\( \Phi = \exists r \cdot N; \Phi_f \text{ where } f(x, r) = \Phi_f \in N. \)

Given \( [\checkmark, S_0, h_0] \leadsto_m [\checkmark, S, h, \text{Norm}(\_)] \models N, \) the semantics of \( \Phi \) is:
\[ [\checkmark, S_0, h_0] \leadsto_m [\checkmark, S_3, h_3, R_3] \models \Phi_e \]

As we either lookup \( f \) in the store or the history and straightforwardly execute it, the conclusion follows from the induction hypothesis on \( e_f. \)

- \( e \) is of the form \( \text{match}[\delta] \) \( e \) with \( \mathcal{H}. \)

Based on the promise, if \( [S, h, e] \longrightarrow [S_2, h_2, R_2] \) then \( [\checkmark, S_0, h_0] \leadsto_m [\checkmark, S_2, h_2, R_2] \models \Phi, \)
therefore if \( [S, h, \text{match}[\delta] \) \( e \) with \( \{ \text{pat}_i \Rightarrow e_i \}_{i=1}^n] \longrightarrow [S_1, h_1, R_1] \) then
\[ [\checkmark, S_0, h_0] \leadsto_m [\checkmark, S_1, h_1, R_1] \models \text{try}[\delta](\Phi) \text{ catch } \mathcal{H}_b. \]

Since the try-catch reduction is proven sound in Theorem 5.1, and there is a promise that \( \text{try}[\delta](\Phi) \text{ catch } \mathcal{H}_b \leadsto \Phi', \) therefore, we have \( [\checkmark, S_0, h_0] \leadsto_m [\checkmark, S_1, h_1, R_1] \models \Phi'. \)

- \( e \) is of the form \( \text{perform } E(x). \)

\( e \) evaluates as follows:
\[ [S, h, \text{perform } E(x)] \longrightarrow [S_2, h_2, R_2] \]
where \( (S_2, h_2, R_2) = (S, h, \text{Eff}(E(S(x)), (\lambda y \rightarrow y, S))). \)

From \( \vdash \{ N \} \text{perform } E(x) \{ \Phi \}, \) using the rule \([FV-Perform], \)
\( \Phi = \exists r \cdot N; E(x, r). \)

Given \( [\checkmark, S_0, h_0] \leadsto_m [\checkmark, S, h, \text{Norm}(\_)] \models N, \) the semantics of \( \Phi \) is:
\[ [\checkmark, S_0, h_0] \leadsto_m [\checkmark, S_3, h_3, R_3] \models \Phi \]
where \( (S_3, h_3, R_3) = (S, h, \text{Eff}(E(x, r), \text{ens}[r \text{ emp}])) \) for some \( v. \)

Thus \( S_3 \supseteq S_2, h_3 = h_2, \) and \( R_2 = R_3 \neq \text{Err} \) because they are both effect results with input \( S(x) \) and result given by a future resumption.

\( \Box \)
B.4 Soundness of Entailment

Theorem 6.1 (Soundness of Entailment Rules). If the entailment checking proves that an entailment \((P_A \vdash \Phi_1 \subseteq \Phi_2 \Rightarrow Q_F)\) is valid, for all \(S, h, SH_1\) and \(SH_2\), if \(\{[S, h] \sim_{m}^{\text{set}} SH_1 \vdash \Phi_1 \land P_A\} \) and \(\{[S, h] \sim_{m}^{\text{set}} SH_2 \vdash \Phi_2 \land Q_F\}\), then \(SH_1 \subseteq SH_2\) holds.

Proof. By induction on the structure of the entailment rule, elaborated in Appendix B.4 [TR 2024].

Proof. By induction on the structure of the entailment rule.

1. Given an entailment \((P_A \vdash \Phi_1 \lor \Phi_2 \Rightarrow Q_F)\), based on the premises of the rule [Entail-LHS-OR],
   \(\{[S, h] \sim_{m}^{\text{set}} SH_1 \vdash \Phi_1 \land P_A\}, \{[S, h] \sim_{m}^{\text{set}} SH_2 \vdash \Phi_2 \land P_A\}\), and \(SH_1 \subseteq SH_2\), and
   \(\{[S, h] \sim_{m}^{\text{set}} SH_3 \vdash \Phi_1 \land Q_F\}\), and \(SH_1 \subseteq SH_3\), and
   since \(\Phi_1 \land P_A\) \(\lor\) \(\Phi_2 \land P_A\), we have \(SH_3 \subseteq SH_3\), and
   since \(\Phi_1 \land Q_F\) \(\lor\) \(\Phi_2 \land Q_F\), we have \(SH_2 \subseteq SH_3\); hence \(SH_1 \subseteq SH_2\).

2. Given an entailment \((P_A \vdash \emptyset \Rightarrow Q_F)\), based on the premises of the rule [Entail-RHS-OR],
   \(\{[S, h] \sim_{m}^{\text{set}} SH_1 \vdash \emptyset \land P_A\}, \{[S, h] \sim_{m}^{\text{set}} SH_2 \vdash \emptyset \land Q_F\}\), and \(SH_1 \subseteq SH_2\), and
   since \(\emptyset \land P_A\) \(\lor\) \(\emptyset \land Q_F\), we have \(SH_3 \subseteq SH_2\); hence \(SH_1 \subseteq SH_2\).

3. Given an entailment \((P_A \vdash \Theta_1 \Rightarrow \Theta_2)\), based on the premises of the rule [Entail-Flow],
   \(\{[S, h] \sim_{m}^{\text{set}} SH_1 \vdash \Theta_1 \land P_A\}, \{[S, h] \sim_{m}^{\text{set}} SH_2 \vdash \Theta_2 \land P_A\}\), and \(SH_1 \subseteq SH_2\), and
   since \(\Theta_1 \land P_A\) \(\lor\) \(\Theta_2 \land P_A\), we have \(SH_3 \subseteq SH_2\); hence \(SH_1 \subseteq SH_2\).

4. Given an entailment \((P_A \vdash N_1 \Rightarrow N_2)\), where \(N_1 = (\exists x^* \cdot \text{req} P_2 \text{ ens } Q_2)\) and \(N_2 = (\exists y^* \cdot \text{req} P_2 \text{ ens } Q_2)\), based on the premises of the rule [Entail-Norm],
   \(\{[S, h] \sim_{m}^{\text{set}} SH_1 \vdash \exists x^* \cdot \text{req} P_2 \text{ ens } Q_2\}, \{[S, h] \sim_{m}^{\text{set}} SH_2 \vdash \exists x^* \cdot \text{req} P_2 \text{ ens } Q_2\}\), and \(SH_1 \subseteq SH_4\), and
   \(\{[S, h] \sim_{m}^{\text{set}} SH_3 \vdash \exists y^* \cdot \text{ens } Q_2 \land Q_F\}, \{[S, h] \sim_{m}^{\text{set}} SH_4 \vdash \exists y^* \cdot \text{ens } Q_2 \land Q_F\}\), and \(SH_1 \subseteq SH_4\), and
   since \(\exists x^* \cdot \text{req} P_2 \text{ ens } Q_2\) \(\lor\) \(\exists y^* \cdot \text{ens } Q_2 \land Q_F\), we have \(SH_3 \subseteq SH_4\); hence \(SH_1 \subseteq SH_2\).

5. The proofs for rules [Entail-Unfold-LHS], [Entail-Eff], [Entail-Unfold-LHS], [Entail-HO], and [Entail-Try-Catch] are similar to the proof for [Entail-Flow] and [Entail-Norm] defined above, as they are all established based on the concatenation of staged flows.

\[\square\]
C  

C.0.1 Encoding the state monad. One of the benefits of algebraic effects is to separate the logic (defined in the client functions) from side-effects (defined in the handlers). As shown in Fig. 37, we encode the state monad using effects \texttt{Read} and \texttt{Write}. The client function \texttt{read_n_write} reads the state and saves the value to \(x\); writes back to the state using \(x+1\); then reads the state again, which is as described using ESL on line 5. The forward reasoning concludes the specification for \texttt{state_handler}, shown on line 11, where the local state \(i\) ends up with pointing to 1 and the program returns 1.

\begin{verbatim}
1 \texttt{effect Read : int}
2 \texttt{effect Write : int -> unit}
3 let read_n_write ()
4 (* read_n_write(res) = \exists x. Read(x); Write(x+1,()); \exists r. Read(r); ens[res] res=r *)
5 = let x = perform Read in
6 perform (Write (x+1)); (* the Write effect returns () *)
7 perform Read
8 let state_handler ()
9 (* state_handler(res) = \exists i. ens[res] i \rightarrow 1 \land res=1 *)
10 = let i = ref 0 in
11 match read_n_write () with
12 | v -> v |
13 | effect Read k -> resume k !i
14 | effect (Write v) k -> i := v; resume k ()
15
16 let write_handler j
17 (* write_handler(j, ret) = \exists x. Read(x); req j \rightarrow_\_ ens j \rightarrow x+1; \exists r. Read(r); ens[ret] ret=r *)
18 = match read_n_write () with
19 | v -> v | effect (Write v) k -> j := v; resume k ()
20
21 let read_handler ()
22 (* read_handler(res) = \exists i. ens[res] i \rightarrow 1 \land ret=1 *)
23 = let i = ref 0 in
24 match (write_handler i) with
25 | v -> v | effect Read k -> resume k !i
26

\end{verbatim}

C.0.2 Nested handlers. Continuing with the state monad example in Fig. 37, here in Fig. 38, we put the handling of \texttt{Read} and \texttt{Write} operators into nested handlers. In particular, \texttt{write_handler} takes a symbolic state reference \(j\); and when handling the function call \texttt{read_n_write()} , it instantiates the \texttt{Write} effect stage, with a flow \(req \ j \rightarrow_\_\_\) , and ensures \(j \rightarrow x+1\) in the subsequent stage. Subsequently, when \texttt{write_handler} is handled with the state reference \(i\) as the argument, the handler in \texttt{write_handler} instantiates the \texttt{Read} effect stages, and finally concludes a normal-flow.

\begin{verbatim}
17 let write_handler j
18 (* write_handler(j, ret) = \exists x. Read(x); req j \rightarrow_\_ ens j \rightarrow x+1; \exists r. Read(r); ens[ret] ret=r *)
19 = match read_n_write () with
20 | v -> v | effect (Write v) k -> j := v; resume k ()
21
22 let read_handler ()
23 (* read_handler(res) = \exists i. ens[res] i \rightarrow 1 \land ret=1 *)
24 = let i = ref 0 in
25 match (write_handler i) with
26 | v -> v | effect Read k -> resume k !i
27
Fig. 38. Handling state operators using nested handlers.
\end{verbatim}
C.0.3 Memory Cell with Exchange. As shown in Fig. 39, there exists a mutable memory cell at location \( l \) in the heap, and suppose that, instead of offering direct access to this location, one wishes to install a handler for an exchange effect. This handler writes a new value into the memory cell and returns its previous value.

```plaintext
effect Exchange : int -> int

let exchange (m: int) =
  (* exchange(m, res) = \exists r. Exchange(m, r) ; ens[res] res=r *)
  perform (Exchange m)

let exc_handler (l: int ref) (new: int)
  exc_handler (l, new, res) =
  \exists old. req l \mapsto old ens[res] l \mapsto new \land res=old
  match exchange new with
  | v -> v
  | effect (Exchange n) k ->
    let old = !l in
    l := n;
    resume k old
```

Fig. 39. A handler for exchanging values.

The specification for exchange shows that it performs Exchange with the input value \( m \) as the argument, then returns the resumed value. The specification for exc_handler takes two arguments: the reference to the heap location \( l \) and the new value to be assigned to \( l \); and its precondition requires \( l \) is currently allocated with value old, then ensures a normal return with \( l \) pointing to new. Thus, this program states that, provided the location \( l \) currently contains some value, the client may perform the effect Exchange. If the handler wishes to reply, it must update the memory location \( l \) with the value \( new \) and reply by returning the value \( old \). During this interaction, the unique ownership of the memory location is transferred from the client to the handler and back.

```plaintext
effect Inc : int -> int

let rec sumEff n
  (* sumEff(n, res) = ens[res] n=0 \land res=0 \lor
  \exists r1. ens n>0; Inc(n, r1); \exists r2. sumEff(n-1, r2); ens[res] res=r1+r2 *)
  = if n == 0 then 0
  else let r = perform (Inc n) in r + sumEff(n-1)

let main i n
  (* main(n, ret) = \exists z. req i \mapsto z \land n \geq 0
  ens[ret] i \mapsto z+(n(n+1)/2) \land ret=n *)
  = match sumEff n with
  | v -> v | effect (Inc v) k -> i := !i+v;
```

Fig. 40. Example with Inductive Predicate.

C.0.4 Inductive predicates for ESL. We also demonstrate that our framework could support user-defined inductive predicates for ESL, in the form of sumEff \((n, res)\). This predicate denotes an effectful specification whose properties are captured by the parameters \( n \). As shown in Fig. 40, at lines 4-5. The inductive predicate sumEff, summarizes the specification of function sumEff that
Finally we derive the actual behavior of the handler in and generate the entailment for verifying

\[ \text{try} \exists res \cdot \text{ens} n>0; \text{sumEff}(n, \text{res}) \neq \text{try}' \cdot \text{ens}[r'] r'=\text{res+acc} \quad \text{catch} \quad \mathcal{H}_0 = \exists r \cdot \text{inv}(n, \text{acc}, r) \]

Fig. 41. A try-catch lemma for the recursive sum function in a deep handler

\[

\end{align*}
\]

Fig. 43. Try-catch reduction when handling sumEff, and the entailment generated for function main

A concurrent round-robin scheduler. Fig. 44 defines a user-level threading system using effect handlers, which has a top-level run function and provides a fork primitive to spawn off a new concurrent task and a yield primitive to yield control to some other task. Specifically, the Fork effect takes a suspended computation represented as a function of type unit \(\rightarrow\) unit and returns a unit; while the Yield effect is unparameterized and returns a unit value when performed.

A FIFO mutable queue is employed to enable the round-robin scheduling. The heavy lifting is done by the spawn function, which runs the given task f in an effect handler. If f returns a value, we
```ocaml
let enqueue f queue = Queue.push f queue

let dequeue queue
  = if Queue.is_empty queue then ()
  else resume (Queue.pop queue) ()

let rec spawn (f : (unit -> unit)) run_q
  = match f () with
      | x -> dequeue run_q
      | effect Yield k -> enqueue k run_q ; dequeue run_q
      | effect (Fork f') k -> enqueue k run_q ; spawn f' run_q

let run main
  = let run_q = Queue.create ()
    in spawn main run_q
```

Fig. 44. A concurrent scheduler via Fork and Yield effects

dequeue and run the next task from the scheduler queue. If f performs the Yield effect, the current task is suspended (inserted into the queue), and the next task from the scheduler queue runs. If the effect is Fork f’, the current task is suspended, and the new task is executed immediately via a tail call to spawn with f’. We aim to prove that taking any task f and queue run_q, the spawn function eventually terminates, and handles all the Fork or Yield effects in f and run_q, which indicates that the handler does not leak any effects.

```ocaml

\[
\text{any\_queue}(\text{queue}, m) = \exists q \cdot \text{queue}\rightarrow q \land \text{effNo}(q) = m \land m \geq 0
\]

\[
\text{non\_empty\_queue}(\text{queue}, m) = \exists q \cdot \text{queue}\rightarrow q \land \text{effNo}(q) = m \land m > 0
\]

\[
\text{empty\_queue}(\text{queue}) = \exists q \cdot \text{queue}\rightarrow q \land \text{effNo}(q) = 0
\]

\[
\text{enqueue}(f', \text{queue}, r) = \exists m, m', w \colon \text{req any\_queue}(\text{queue}, m)
\]
\[
\ens[r] \text{non\_empty\_queue}(\text{queue}, m') \land \text{effNo}(f') = w \land w > 0 \land m' = m + w \land r = ()
\]

\[
\text{queue\_pop}(\text{queue}, r) = \exists m, m', w, f' \colon \text{req non\_empty\_queue}(\text{queue}, m)
\]
\[
\ens[r] \text{any\_queue}(\text{queue}, m') \land \text{effNo}(f') = w \land w > 0 \land m' = m + w \land r = f'
\]

\[
\text{dequeue}(\text{queue}, r) = \text{req empty\_queue}(\text{queue}) \ens[r] \text{empty\_queue}(\text{queue}) \land r = ()
\]
\[
\lor \exists f' \colon \text{queue\_pop}(\text{queue}, f') ; \text{continue}(f'(), r) ; \ens[r] r = ()
\]

Fig. 45. Modeling the mutable queue and specifications for the queue operations
```

To facilitate the proof, we define predicates for queues and ESL specifications for queue operations in Fig. 45, where an uninterpreted function effNo denotes the number of unhandled effects contained in a queue instance or a given task. Next, Fig. 46 defines a generic modeling of the terminating task
f and the specification for the spawn function. We notice that there are three kinds of behaviors of spawn:

- Base case: when both the task and the queue contain no effects, it returns a unit;
- Inductive case I: when the task contains no effects, but the queue is nonempty, it recursively calls spawn with an updated queue, which has fewer effects than the original queue;
- Inductive case II: when the current task f contains some effects, it recursively calls spawn with f' and an updated queue. In addition, the total number of effects contained in f' and the updated queue is strictly smaller than the effects contained in f and the original queue.

\[
\text{task}(f) = \text{ens}[r] \ \text{effNo}(f)=0 \land r=() \land \exists r_1, w, f_2; \text{ens[}r]\text{effNo}(f)=w \land \text{effNo}(f_2)=w-1 \land w-1>0, \ \text{Yield}(r_1); \ \text{task}(f_2); \ \text{ens[}r]\text{r}=() \\
\lor \exists r_1, w, w_1, w_2, f_1, f_2; \text{ens effNo}(f)=w \land \text{effNo}(f_1)=w_1 \land w_1>0 \land \text{effNo}(f_2)=w_2 \land w_2>0 \land (w_1+w_2=w-1), \text{Fork}(f_1, r_1); \ \text{task}(f_2); \ \text{ens[}r]\text{r}=() \\
\lor \exists m' m' w w' f f'; \text{req non_empty_queue}(run_q, m) \land \text{effNo}(f)=0; \text{ens[}r]\text{any_queue}(run_q, m') \land \text{effNo}(f')=w' \land w'>0 \land w'+m'=m \land m'<m; \ \text{spawn}(f', run_q, r) \\
\lor \exists m' m' w w' f f'; \text{req any_queue}(run_q, m) \land \text{effNo}(f)=w \land w>0; \text{ens[}r]\text{any_queue}(run_q, m') \land \text{effNo}(f')=w' \land w'>0 \land (w'+m')<(m+w); \text{spawn}(f', run_q, r) \\
\text{spawn}(f, run_q, r) = \text{req empty_queue}(run_q) \land \text{effNo}(f)=0; \text{ens[}r]\text{r}=() \\
\lor \exists m' w' f'; \text{req non_empty_queue}(run_q, m) \land \text{effNo}(f)=0; \text{ens[}r]\text{any_queue}(run_q, m') \land \text{effNo}(f')=w' \land w'>0 \land w'+m'=m \land m'<m; \text{spawn}(f', run_q, r) \\
\lor \exists m' w w' f f'; \text{req any_queue}(run_q, m) \land \text{effNo}(f)=w \land w>0; \text{ens[}r]\text{any_queue}(run_q, m') \land \text{effNo}(f')=w' \land w'>0 \land (w'+m')<(m+w); \text{spawn}(f', run_q, r)
\]

Fig. 46. Specifications for any execution task f and the spawn function

With this case analysis, we can see that the handler recursively calls spawn with new task f and update queue. The termination proof has two stages: 1) when f has a positive number of effects, the total number of effects in f, and the queue works as a ranking function and decrees at each recursive call to spawn; 2) when f has no effects, the length of the queue works as a ranking function and decrees at each recursive call to spawn. Altogether, we prove the termination of the handler, given that the given task is terminating, i.e., the task generates a finite number of effects. In addition, since the base case indicates an empty queue, all the effects will eventually be handled, and there will be no leaked effects. All the reasoning and proving are automated in our system.
